Of the 542 questionnaires mailed, 439 (81%) were completed. The group response rates were physician specialists, 81% (114 of 140); primary care physicians, 78% (234 of 301); and ICPs, 90% (91 of 101). Of the 91 responding ICPs, 85 were nurses and 6 were physicians. There were no significant differences between responding and nonresponding physicians in years of experience, location of practice (rural or urban), or type of practice (specialist or primary care).

Physicians in larger hospitals were more likely than others to have cared for at least one person with AIDS (those in hospitals with more than 300 beds, 62%; with 101 to 300 beds, 51%; with 100 beds or fewer, 25%; $P < .001$ chi-square for linear trend). Forty-three percent of the surveyed primary care physicians, 72% of the physician specialists, and 64% of the ICPs

Practice in the three largest urban counties	29	(79)	280	(48)	1.6	1.3–2.1
Do not report if think case has already been reported	27	(85)	260	(54)	1.6	1.3–1.9
Think case report forms too long	27	(26)	267	(18)	1.5	0.7–2.9
Have discrimination concerns	28	(46)	286	(39)	1.2	0.8–1.8
Have confidentiality concerns	28	(61)	286	(54)	1.1	0.8–1.6
Have liability concerns	28	(32)	284	(34)	1.0	0.6–1.7
Work in hospitals with						
>300 beds	14	(48)	149	(53)		
101–300 beds	11	(38)	84	(30)	0.7	0.4–1.6
≤100 beds	4	(14)	46	(17)	1.1	0.4–3.1

[a]Seventeen physicians did not respond to these questions; 9 indicated they report AIDS cases sometimes (25% to 75% of the time).
[b]"Rarely or never" means they report AIDS cases less than 25% of the time.
[c]"Usually or always" means they report AIDS cases 76% to 100% of the time.
[d]PR = Prevalence ratio of physicians who rarely or never report AIDS cases vs those who usually or always report.

had participated in the care of at least one person with AIDS. The numbers of AIDS patients cared for by physician specialty are listed in Table 1.

Seventy-nine percent of the physicians and 80% of the ICPs indicated that HIV infection as well as AIDS should be reportable by name to the health department. Only 28 physicians (8%) indicated that HIV infection should not be reportable by name.

Fifty-nine percent of the physicians and 63% of the ICPs indicated that primary care physicians have the principal responsibility for reporting AIDS cases. There was no significant difference in responses to this question from physician specialists and primary care physicians. Only 7% of the physicians and 17% of the ICPs indicated that ICPs have the primary responsibility for reporting AIDS cases; 9% of the physicians and 10% of the ICPs indicated that the laboratory has the primary responsibility.

Eighty-eight percent of the physicians surveyed and 83% of the ICPs indicated that they report AIDS cases most of the time or always. However, only 44% of the physicians and 64% of the ICPs report AIDS cases they think may have been reported in other states.

Physicians who replied that they rarely or never report AIDS cases were more likely than physicians who replied that they usually or always do so to indicate confusion about both the need to report cases that may have been previously reported and responsibility for reporting, a belief that information required for reporting is often not on the chart, and urban residence (Table 2). However, physicians who reported that they rarely or never report AIDS cases were not more likely to report concerns about confidentiality, legal liability associated with reporting, potential discrimination, length of the AIDS case report form, and hospital bed size (Table 2).

We used a backward stepwise logistic model to present the characteristics that are the best predictors of physicians who would rarely or never report AIDS cases (see Table 3).

Discussion

It is evident from this survey that a substantial percentage of physicians and ICPs in South Carolina have cared for AIDS patients. Similar trends may be observed in other states with low to moderate AIDS prevalence as the highest annual percent increases in AIDS cases continue to be seen in the smaller communities away from urban centers.[9] Therefore, AIDS surveillance in the less urban states is becoming increasingly important.

According to most physicians and ICPs surveyed, physicians have the principal responsibility for reporting. In South Carolina, at the time of this study, 55% of

AIDS cases were reported by physicians, 14% by ICPs, 11% by death certificate review, 6% by health department medical record review, and 14% by other means. Other authors have also indicated that practicing physicians are the key to effective surveillance of infectious diseases.[10]

Surveillance has focused on AIDS, but HIV reporting is becoming more important as preventive therapies are developed for infected patients and as health departments are becoming more involved in the clinical follow-up, case management, and funding of HIV-related disease. Health planners need to know the number and characteristics of individuals infected with HIV to plan for the cost and distribution of these services. In addition, HIV reporting has helped the development of quality partner notification and CD4 lymphocyte staging services for patients in South Carolina.[11–13]

The findings of the present study have helped DHEC surveillance personnel educate physicians and ICPs about AIDS reporting and further improve gains in active AIDS surveillance.[14] □

TABLE 3—Characteristics That Are the Best Predictors of Physicians Who Would Rarely or Never[a] Report AIDS Cases (n = 254)

Characteristics of Nonreporters	Estimate of PR[c]	95% CI
Do not report if think case has been reported in another state	16.9	2.1–134.7
Practice in the three largest urban counties	4.4	1.3–15.2
Do not think required medical information is on chart	3.8	1.4–10.7
Do not feel responsible for reporting	3.8	1.3–10.9
Have discrimination concerns	3.0	1.1–8.5

[a]"Rarely or never" means they would report AIDS cases less than 25% of the time.
[b]Respondents who did not answer all the questions included in the model (n = 94) were excluded from this analysis.
[c]Estimate of prevalence ratio (PR) of physicians who rarely or never report AIDS cases vs those who usually or always report, based on odds ratio calculated with logistic regression.

Acknowledgments

We wish to thank Ms. Julie Lumpkin for her review and excellent technical advice.

Education

Physician education consisted of a grand round lecture covering the causes, evaluation, and management of falls. Community nurses were given a similar lecture emphasizing how to perform regular assessments for fall hazards in the home and recommend appropriate environmental modifications.

The thrust of our lay education was to generate awareness about falls, the importance of reporting them to appropriate health care professionals, and making home environments safer. We published articles in the community newspaper on falls and prevention. A health educator from the hospital was trained to lecture at senior centers throughout the county; a set of slides showing common hazards in the home accompanied the talks. These sessions incorporated a discussion period that allowed older people to ask for further information on falls and advice on how to make their homes safer.

Identification

To help identify fallers and those at risk, physicians and nurses were trained to question patients about falls during routine examinations. Hospital emergency room personnel were encouraged to use E codes, a subset of the ICD-9-CM codes specifically developed to identify the external cause of fall injuries, and to refer persons for physician or nurse follow-up.

During community lectures at senior centers, the health educator routinely asked whether any older persons in the audience had fallen in the past few months, took names of those people who responded affirmatively, and referred fallers to their primary providers for evaluation.

Community Services

A device bank was initiated to collect (from the community), store, and dispense unused or discarded devices (e.g., grab bars, toilet risers, bath seats) for people unable to afford them. A service was set up in which volunteers from community organizations helped older people make any necessary environmental modifications (e.g., installation of devices such as grab bars and elimination of hazardous conditions) in their homes.

Evaluation

After 1 year, we evaluated the program's effectiveness. Both physicians and nurses in the community stated that they had a greater understanding of falls. They perceived that identifying persons with falls and correcting the underlying factors responsible decreased fall risk and enhanced mobility. A review of 28 persons who had been evaluated for multiple falls verified this impression. Many suffered from several underlying medical problems (e.g., uncontrolled hypertension, electrolyte imbalance, parkinsonism, adverse drug effects), and many cited environmental hazards that were responsible for their falling episodes. Once these problems were addressed and corrected, falls were reduced. We have followed this group over a 2-year period, interviewing them on a monthly basis. To date, 75% have experienced no additional falling episodes.

The response from the broader community of older persons has been equally positive. Approximately 1500 persons have been reached at the senior centers. They generally report that the lectures have given them greater knowledge about falls and ability to identify potential fall hazards in their home environments. Although the device bank and home modification program are still in an early stage, people have appreciated the availability of devices and assistance in their installation.

This project can serve as a model of an effective low-cost fall prevention program. With the exception of one-time only grant support ($20 000) for a gerontologist to help develop the program, the costs were absorbed by the hospital (e.g., the educational slide program at a cost of $100) or were negligible. Existing resources (health professionals, community services) were used to develop prevention interventions. Currently, the program is being managed by the health educator, who has replaced the gerontologist. The health educator's salary is paid by third-party reimbursement fees generated from patient evaluations.

The acceptance and usefulness of the program are clearly demonstrated by the fact that community health professionals and organizations (e.g., Public Health Department, Visiting Nurse Service, Area Agency of Aging) have embraced it as a fall prevention measure. The hospital has incorporated the program into its ongoing budget and mainstream services offered. □

Community-Based Case Management of HIV Disease

Fairfax County, Virginia, with a population of more than 800 000, is the most populous political subdivision of the Washington, DC, area. Although metropolitan Washington has consistently ranked fifth nationally in the cumulative incidence of AIDS cases, Fairfax County's share of the total has been only slightly more than 5%, over 80% of whom have been classified as belonging to the gay-bisexual transmission group.

To monitor the incidence of human immunodeficiency virus (HIV) infection in its clinic populations, the Fairfax County Health Department began an expanded program of voluntary testing for antibody during 1986. In June 1987 the county implemented the HIV Case Management Program for residents asymptomatically infected with HIV. The program was designed primarily to serve the low-income, high-risk heterosexual populations, especially those who have engaged in intravenous drug use, and their sexual partners. These individuals are difficult to reach and may pose the greatest danger for continued spread of the virus in the general population. The program is open to the gay-bisexual community as well, but because most have access to other care providers through insurance or special community resources, many opt for care through other sources.

The county's human services agencies—Department of Health, Fairfax-Falls Church Community Services Board, and the Department of Human Development—operate this program jointly. During the past year, by contractual arrangement, a group practice specializing in infectious diseases (Infectious Diseases Physicians, Inc. or IDP) has provided a program for early

TABLE 1—Case Management Program Costs by Agency for Calendar Years 1989 and 1990

	1989 (33 visits, 23 patients)	1990 (45 visits, 36 patients)
Health Department		
Staff	$25 371	$27 823
Laboratory	$ 5555	$ 9000
Subtotal	$30 926	$36 823
Community Services Board	$ 6376	$10 464
Human Development	$ 3125	$ 2235
Total	$42 427	$49 522

Zidovudine therapy for asymptomatic HIV patients. The county health department collaborates with IDP in monitoring these patients until they become symptomatic or require prophylaxis against *Pneumoncystis carinii* infection. At that stage in the disease, patients are no longer followed in the case management program. Fairfax Hospital, under a contract with the county health department, assumes medical and case management responsibility for our patients when their disease becomes symptomatic or their CD4 count falls below 200.

The case management program holds clinics at two geographic sites within the county; the clinics are staffed by personnel from the three participating agencies. The management of patients with HIV infection includes lifestyle counseling to slow the progression of the infection and to prevent its spread to others. A special patient consent form enables members of the interagency team to share patient information with each other, thus facilitating the development of a coordinated plan for the patient's medical care and mental health and social needs. This systematic plan reduces the need for crisis management.

Patients enter the case management program voluntarily. They are referred to the program through the health department's HIV screening and case-finding activities and by private physicians, local hospitals, and HIV/AIDS information services. Before the first clinic visit, the patient provides a detailed medical and social history and blood and urine specimens for routine laboratory examination.

At the initial and subsequent routine visits the patient's history is updated and a thorough clinical examination is performed. Routine laboratory tests include complete blood cell count and differential, urinalysis, serologic tests for syphilis, HIV antigen test, β-2 microglobulin assay, and a helper T lymphocyte (CD4) count. Tests for hepatitis B core antibody and surface antigen are done on the initial visit and subsequently if indicated. Pap smears are done annually on female patients. Chest x-rays are obtained for the initial visit and annually thereafter. Reactivity to purified protein derivative (tuberculin), mumps, and candida antigens is determined by skin test at the initial visit.

Patients are seen every 6 months unless a shorter interval is indicated; those receiving early Zidovudine therapy are seen at intervals set by IDP. At each routine visit the patient is evaluated and counseled by the mental health counselor and, if indicated, the substance abuse counselor. Arrangements are made for separate individual or group counseling sessions as desired. The Human Development team member reviews with the patients their current and future financial requirements and needs for support. Case management program team members meet jointly once a month to review the status of the patients seen during the month and to make recommendations for their future care.

A total of 81 patients entered the case management program between June 1987 and June 1991. Demographic attributes of the patients are as follows:

- Age: Range, 21 to 62 years; median, 30 years
- Sex: Male 51, female 30
- Ethnic group: White, 38; Black, 39; Hispanic, 3; Asian, 1
- Risk group: Male homosexual, 27; intravenous drugs, 34; heterosexual, 20

The characteristics of the 14 patients lost to follow-up were similar to those of the total group. Only one patient, an elderly person with chronic alcoholism, is known to have died. The cause of death was liver failure and HIV was not considered a contributory cause.

Program costs rose only slightly from 1989 to 1990, whereas costs per visit declined (Table 1). The total cost per visit in 1989 was $1285; in 1990, it was $1100. The average for the 2 years was $1179 per visit.

The health department's cost for routine clinic services in 1990 was approximately $400 per visit, which included $200 for laboratory services. The remainder of the staff costs were devoted to intake, patient follow-up, and case review. The increase in laboratory costs in 1990 reflects the greater use of CD4 counts for patients receiving early Zidovudine therapy. Most clinics operated at considerably less than optimum patient load; the operating costs per visit should decline appreciably with increasing numbers of patients per clinic.

The collaborative program with IDP for early therapy with Zidovudine entails additional annual costs of $400 per patient for physicians' fees. At present the state of Virginia is supplying the Zidovudine if the patient is unable to pay for the drug; thus this cost is not included in the direct costs of the program.

Although the future course of the HIV epidemic in the United States is still uncertain, current evidence suggests that the virus has begun to spread in the young heterosexual population in many areas of the country. There will be an increased need for adaptive programs at the community level that will combine expanded case-finding activities with case-management programs similar to the one described here.

As the next step in this program, we are exploring new methods of outreach to intravenous drug users and to the young sexually active heterosexual population. Improved methods will be required if there is to be effective intervention in this epidemic. Programs like this can provide a useful community focus for these broader efforts. □

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc, 1015 Fifteenth St, NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50 000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health*, 1015 Fifteenth St, NW, Washington, DC 20005.

Information on Manuscript Preparation is published monthly in the Journal. The Journal publishes reports of original research, research methods, program evaluations, analytic reviews, including health policy analysis, and reports for special departments. A paper is considered with the understanding that it or its essential substance neither has been published nor is under consideration elsewhere.

Subscription price, individual, is $80/year US, $120/year international; **institutional,** $160/year US, $240/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to *American Journal of Public Health*, 1015 Fifteenth St, NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Schultz, Advertising Manager, APHA, 1015 Fifteenth St, NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Public Health Policy Forum

Health and the Environment in the 1990s

Richard Doll, DM, FRS

ABSTRACT

Expectation of life at birth provides a simple measure of the state of health of a country. Differences in the expectation are examined in the United States over time and between males and females and Whites and non-Whites, and worldwide between market and nonmarket developed countries, and between developed and developing countries. The principal factors responsible for the trends and the current differences are changes in the social and physical environment, in personal behavior, and in medical care, and their relative importance is assessed. It is concluded that, at present, the principal environmental hazards worldwide are those associated with poverty of individuals within the market economies and of communities in the developing countries and that in the future, they will be the effects of overpopulation and the production of greenhouse gases. (*Am J Public Health.* 1992;82:933–941)

Health, according to the World Health Organization (WHO), is defined as a state of complete physical, mental, and social well-being. This is a fine and inspiring concept and its pursuit guarantees health professionals unlimited opportunities for work in the future, but it is not of much practical use for specialists in public health medicine who need to compare the states of health in different communities and at different times and who consequently need to give them numerical values. I shall therefore use the term *health* in the limited sense of a state distinguished by the absence of disease or of physical or mental defect, that is, the absence of conditions that detract from functional capacity whose incidence can be measured objectively. And because morbidity and mortality are so closely related, I shall assess health largely in terms of mortality and years of expectation of life, for which objective evidence is available for long periods throughout most of the world.

As to environment, I shall start with the simple definition of the *Oxford English Dictionary:* namely, "the conditions under which any person lives." We can, however, limit the conditions to those whose effects people are individually unable to control, and so exclude such conditions as the availability of tobacco and, in high-income societies, of a high-fat diet, as people exposed to them can choose alternative diets and whether or not to smoke. By excluding these conditions I do not exclude the effects of malnutrition in low-income societies in which a healthy diet may be beyond people's means; in these circumstances, a nutritionally inadequate diet must be regarded as a condition of the society in which the people live.

Even with these restricted definitions, the subject is still so vast that I can deal with much of it only in outline. I shall therefore describe first and very briefly the trends in mortality in the United States, as representative of what the World Bank calls the market economy countries of the industrialized world,[1] and the comparative conditions in the non–market economy industrialized countries and the developing countries. I shall examine in each case the environmental factors that have contributed to the trends and to the differences between them. Second, I shall seek to justify my statement that the changes that occur in each part of the world affect conditions everywhere else. I shall conclude by suggesting some priorities for the selection of the environmental factors that we should now most energetically seek to control.

Health and the Environment in the United States

Expectation of Life

The simplest measure of the state of health of a country is the expectation of life at birth of its citizens. The trend in expectation of life at birth in the United States since the beginning of the century is shown in Figure 1, separately for males and females. The data for the years before 1928 refer only to the limited number of registration states (10 plus the District of Columbia until 1911 and then 30 plus the District of Columbia until 1927), but the lack of sharp breaks in the trend suggests

This paper was submitted to the Journal February 20, 1992, and accepted March 24, 1992.

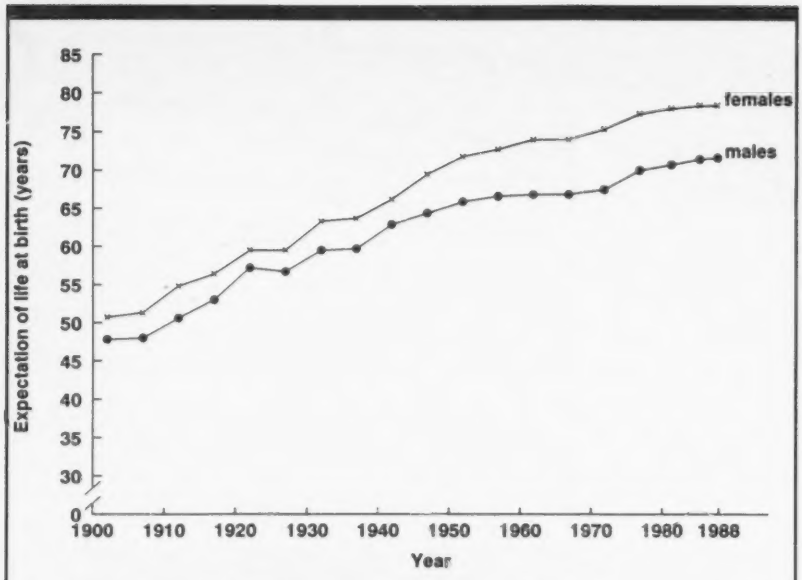

FIGURE 1—Trend in expectation of life at birth in the United States, 1900 to 1985, for males (●——●) and females (x——x).

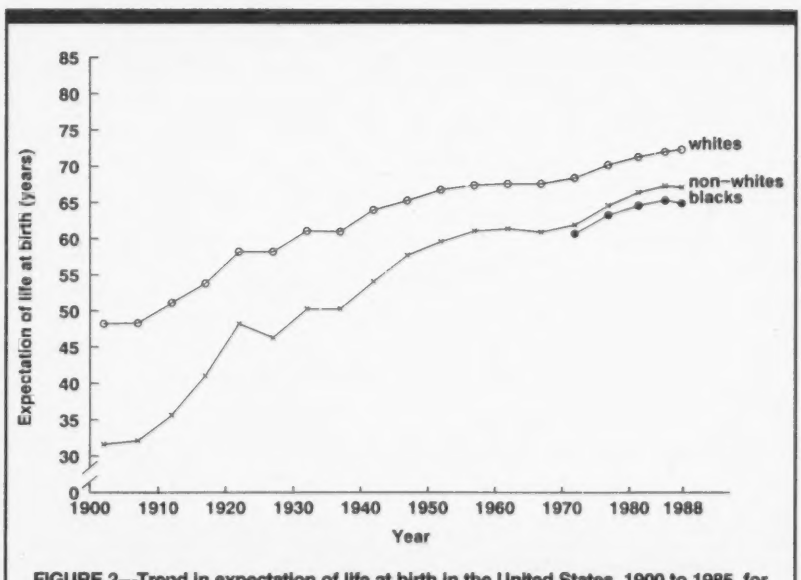

FIGURE 2—Trend in expectation of life at birth in the United States, 1900 to 1985, for Whites (○——○), non-Whites (x——x), and Blacks (●——●).

that the pre-1928 figures were reasonably representative of the whole country. In both sexes increases have occurred throughout the period, apart from brief intervals in the late 1920s, 1930s, and 1960s. In total the increases have been large. The increase has been greater for females than for males, both absolutely and proportionately, and the female advantage of nearly 3 years in 1900 to 1904 has more than doubled to nearly 7 years in the late 1980s.

In all industrialized countries the state of health varies between social groups, and this has been particularly easy to see in the United States because of the publication of vital statistics by race and the broad correlation between race and social status. The differences in the expectation of life between White and non-White males at different times in this century are shown in Figure 2. The 1900 advantage of nearly 17 years for White males over non-White males (almost all of whom at that time were Black) has progressively diminished, but in 1988 the difference was still about 5 years or, if comparison is made only with Blacks, for whom separate data are now published, about 7 years.

Factors Responsible for Trends

These increases in the expectation of life have been brought about primarily by a reduction of over 90% in the mortality rate for infants and children younger than 5 years of age, which was 30% at the start of the century and is now only 2%. As a result, the increase of 23 years in the expectation of life at birth corresponds to an increase of only 14 years for those who survive to reach the age of 5. Reductions in mortality have, however, occurred at all other ages, as is shown in Figure 3; even for those older than 80 years of age the reduction has been as much as a third.

The reasons for the reduced mortality in the early decades of the century are well known and not open to serious question, except as regards the relative importance of the various factors responsible for the reduction. These were essentially factors that diminished the risk or the fatality of infection, including improved nutrition, smaller family size, better provision of water uncontaminated with feces, control of the vectors of malaria, pasteurization of milk, maternal education in the care of infants, and immunization. Treatment of infection played little if any part in the reduction of mortality, as treatment was generally ineffective until the introduction of the sulfa drugs in 1936. The principal roles in reduction of mortality must be attributed to the improved environment (defined as the conditions under which people lived) brought about by the increased standard of living consequent on industrial development and, secondarily, to the application of knowledge of the causes of disease and the way disease could be prevented. With the advent of sulfa drugs and the development of a series of antibiotics following the first use of a laboratory preparation of penicillin in 1941, therapy has played an increasingly important role in the control of infection and, more recently, in the treatment of cancer and ischemic heart disease. Other factors are better anesthesia and postoperative care, further immunization, and the discovery of the means to reduce substantially the age-specific risk of degenerative disease by the avoidance of smoking and the reduction of blood pressure and of blood low-density-lipoprotein cholesterol.

The longer expectation of life of females is a universal phenomenon in industrialized countries; it is partly genetic in origin and partly behavioral. The widening of the gap between the sexes that began immediately after the Second World War and continued into the 1970s, and its subsequent narrowing (Table 1), can be attributed largely to cigarette smoking being taken up first by men and only later by women. The different trends in mortality from the principal diseases related to smoking (heart disease, respiratory cancer, and chronic obstructive pulmonary disease) could account for most of the difference between the trends in the two sexes from 1950 to 1970 and for all of it from 1970 to 1988 (Table 2).

The factors responsible for the shorter expectation of life of Black Americans than of Whites and for the partial closing of the gap up to 1960 are equally clear, though again difficult to put in hierarchical order. In this case, the direct medical effects of genetic factors operate in both directions, and essentially the whole difference must be attributed to differences in the social environment in which people live, operating sometimes indirectly by modifying behavior and sometimes directly via malnutrition, overcrowding, and a deficiency of medical care.[2-4] The narrowing of the gap, which occurred between 1900 and 1960, can be attributed almost entirely to the differential reduction in mortality in infancy and childhood, as the difference in the expectation of life between Whites and Blacks in adult life has changed relatively little (Table 3). The narrowing of the gap, therefore, was due to the factors referred to previously that improved the health of infants and children in all sections of the community, principally by reducing the risk of infection.

Role of the Environment

These factors have their origins partly in increased scientific knowledge, but at least as much, if not much more, in the changes in the environment that have accompanied the increased wealth produced by industrial and agricultural development, that is, the reduced prevalence of malnutrition and of imperfectly preserved food, the provision of ample water supplies uncontaminated with pathogenic organisms, the reduced prevalence of pathogenic parasites or their vectors, the better housing and smaller families, and the increased opportunities for education. There are, however, other aspects of industrial and agricultural development that have had deleterious effects, for example, the destruction of much natural beauty; the loss of open spaces for exercise; the destruction of natural habitats for many species, leading, in some cases, to their extinction; the widespread distribution of potentially toxic chemicals; and the distribution of other chemicals in nontoxic amounts but on such a scale that the climate of the world is modified. I shall consider the last effect later, as it is its potential for future damage that is most worrying, but we need to consider now how far the dispersal of toxic chemicals may already have harmed health and partially counterbalanced the many benefits of increasing prosperity.

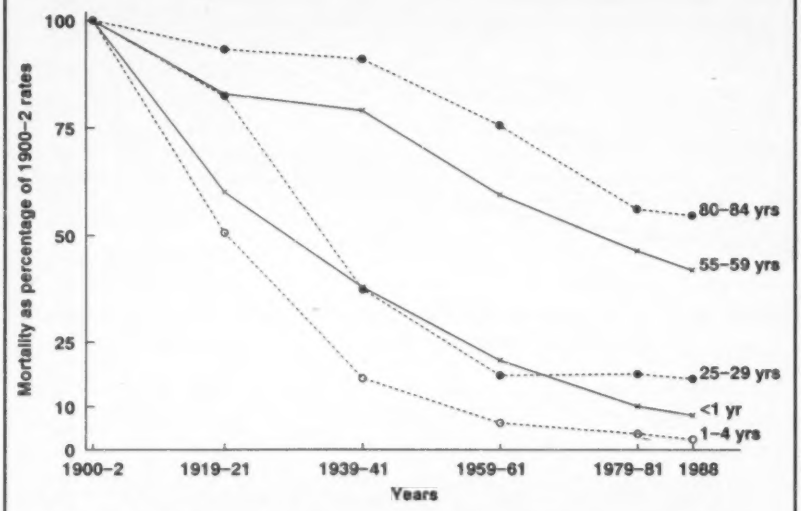

FIGURE 3—Trend in mortality by age in the United States, 1900–1902 to 1988, ages less than 1 year (x——x), 1–4 years (○—○), 25–29 years (●—●), 55–59 years (x——x), and 80–84 years (●—●).

TABLE 1—Expectation of Life at Birth, by Sex: 1900–1924 to 1985–1988

Period	Expectation of Life, y		
	Male	Female	Female Advantage
1900–1924	51.9	55.0	3.1
1930–1944	61.4	64.8	3.4
1950–1954	65.9	71.8	5.9
1960–1964	66.8	73.5	6.7
1970–1974	67.5	75.2	7.7
1980–1984	70.7	77.9	7.2
1985–1988	71.4	78.3	6.9

This problem has given rise to a vast literature, but hard evidence of the material effects on health of the dispersal of toxic chemicals is relatively sparse. What is clear is that industrial developments over the last century have affected health in two ways. First, the pollution in urban air has been reduced—enormously in the case of smoke and substantially in the case of sulfur dioxide—by the use of central heating instead of domestic fires; by the use of natural gas, oil, and electricity as sources of power, instead of coal and wood; and by the control of emissions when coal is burned as a source of energy in industry. Second, complex pollution has been caused by the enormous increase in motor traffic and its accompanying exhaust fumes; by the wide dispersal of natural and artificial chemicals in emissions from factories; by the use of chemical fertilizers, herbicides, and pesticides in agriculture; and by the dispersal of industrial waste. What is less clear is whether, and to what extent, the harm done by the increase in complex pollution outweighs (if it does) the benefits of the reduction in urban air pollution.

The difficulty is that few of these effects have been properly quantified. The pollution of the past (which is still present in the non-market economy countries and in some of the developing countries) caused dense smogs when accompanied by temperature inversions, and these smogs occasionally caused acute increases in mortality from heart and respiratory diseases. One such smog in London in 1952 was estimated to have caused 4000 premature deaths,[5,6] but this was exceptional and the normal annual total pro-

TABLE 2—Mortality from Different Causes, by Sex: 1950 to 1988

Cause of Death	Sex	Mortality per 100 000	Percent change	
		1950	1950–1970	1970–1988
Heart disease, respiratory cancer, and chronic obstructive pulmonary disease	M	498.7	+3.1	−27.3
	F	291.0	−20.7	−16.2
Other	M	554.4	−14.9	−24.1
	F	414.0	−23.1	−27.5

TABLE 3—Expectation of Life at Different Ages, by Race: 1900 to 1981

Age	Period	Expectation of Life, y		
		White	Black	White Advantage
Newborn	1900–1902	49.7	34.1	15.6
	1959–1961	70.9	64.0	6.9
20 years	1900–1902	43.0	36.0	7.0
	1950–1961	53.3	47.9	5.4

duced in this way may have been quite small. The very high concentrations of smoke—which in large towns commonly averaged over 100 $\mu g/m^3$ of particulate matter throughout the year, with a content of 30 to 40 ng/m^3 of benzo(a)pyrene—must have produced some lung cancers, but direct evidence of the size of the effect has never been clearly obtained, particularly for nonsmokers. Extrapolation from industrial exposures suggests that urban exposure may have contributed, in conjunction with other polycyclic hydrocarbons in the air, to some 10% of the lung cancers in populations in cities with average smoking habits.[7,8] If this were so, the reduction in smoke pollution to levels one or two orders of magnitude less could have prevented many hundreds of premature deaths a year.

How much ill health has been produced by the new sources of pollution is even more difficult to estimate. That some has been produced is incontrovertible: for example, the irritation of the eyes and respiratory system by the photochemical smog produced by the action of sunlight on the exhaust fumes of cars, the damage to the developing brain from environmental lead, and a few cases of mesothelioma from the dispersal of asbestos. But whether current levels of sulfur dioxide in combination with nitrogen oxides and the corresponding acids are responsible for more respiratory disease than were the previous higher levels of sulfur dioxide in combination with smoke is impossible to assess directly, as is the total effect on public health of the dispersal of industrial products and waste into air, soil, and water.

One particular type of pollution that has caused much public concern is the pollution of food with residual carcinogenic pesticides. Yet Ames and Gold[9] estimate that the amount of such carcinogens in food is 1800 times *less* than the amount of carcinogens derived from the 54 natural plant chemicals in food that have been similarly tested for carcinogenicity. Another cause of public concern is the dispersal of hazardous industrial waste. This subject has been considered by a Committee of the Boards on Environmental Studies and Toxicity of the National Research Council. The committee concluded that many criticisms could be made of the 21 published reports of the effects on public health of hazardous waste sites, but that the evidence was strong enough in sum to suggest that "hazardous waste sites have produced serious health effects in some populations." On the basis of its review of the published literature, however, the committee was unable to answer the question "whether Superfund and other hazardous-waste programs actually protect human health." Yet "less than 1% of the estimated $4.2 billion spent each year on hazardous waste sites in the United States [during the last 10 years] has been used to evaluate health risks at listed Superfund sites."[10]

Irrespective of the conclusion that may be reached about individual sources of pollution, it is clear that modern industrial and agricultural development has not caused a new epidemic of either of the most serious effects that have most commonly been postulated, namely cancer and congenital anomalies.

The increase in the mortality from cancer at all ages that is sometimes cited as evidence of increasing environmental hazards is due to an increase at old ages and can be accounted for in all industrialized countries by the spread of cigarette smoking by men in the middle of the century and by women more recently. When this effect is allowed for properly, the mortality from all other cancers, considered as a group, is decreasing in middle and old age.[11] To detect an effect from new hazards of individual types of cancer we need to examine the trends in incidence and mortality in early middle age (that is, in adults under 50 years of age), as it is in the relatively young that the effect of new hazards is usually first seen. Examination of these trends shows that most of the important cancers are becoming less common in both Britain and the United States, the increase in the recorded incidence of the others is mostly an artifact of screening or the result of behavior that the individual can choose to avoid.[12,13] Only the worldwide increase in cancer of the testis and the small increase in non-Hodgkin's lymphoma that is not attributable to immune deficiency remain unexplained and may possibly be due to new environmental hazards.

Less evidence is available for congenital malformations, and that which is available is difficult to interpret. When changes in prevalence do occur, the evidence—according to Knox and Lancashire,[14] who have made a detailed examination of the trends observed in a large British series between 1964 and 1984—points firmly to changes in case-finding or to infection rather than to toxic agents. In the United States two registers of malformations are organized by the Centers for Disease Control in Atlanta. One covers about 35 000 births a year in metropolitan Atlanta and seeks information from a variety of sources for the first year of the child's life. The other covers about 575 000 births a year in 1200 hospitals throughout the country and seeks information from computerized discharge diagnoses. Both have operated since 1974. Table 4 shows the results obtained for five types of abnormality, which should be easily diagnosed at birth (cleft lip, cleft palate, reduction deformity of limb, esophageal atresia, and anal atresia).[15] The drop in prevalence between 1979 and

1980 in the Atlanta registry was principally due to a decrease in the prevalence of cleft lips and palates, which does not appear to be an artifact of registration and has yet to be explained (M. J. Khoury, personal communication). The larger register, in contrast, showed a small increase in several of these malformations in the early 1980s, which might have been due to a small real increase in prevalence, to improved registration, or to a change in the nature of the hospital populations.

TABLE 4—Trend in Prevalence of Selected Congenital Malformations, 1974 to 1988

Register	Prevalence per 10 000 Infants[a]				
	1974–1976	1977–1979	1980–1982	1983–1985	1986–1988
Atlanta	31.9	30.2	25.9	26.7	23.0

[a]Death rates are averages of rates for males and females.

Health and the Environment in Other Countries

Non–Market Economy Industrialized Countries

When we look at other countries the picture is different—not so different in the non–market economy industrialized countries, but sufficiently different for the total mortality rate adjusted for age to be 41% higher in these countries than in the market economy countries and for nearly all of the cause-specific mortality rates to be higher as well. Mortality in infancy and childhood, however, is low in both types of industrialized countries, and the increased rates in the non–market economy countries affect principally the old. The expectation of life in 1988 and 1989 nevertheless tended to be about 6 years lower in the non–market economy countries than in the market economy countries,[16] as is shown in Table 5.

As Table 6 shows, the greatest relative differences in mortality between the two types of economy are for tuberculosis and complications of pregnancy, but neither contributes importantly to the total. Nearly two thirds of the absolute excess (63%) is due to ischemic heart disease and cerebrovascular disease, the mortality of which has been decreasing in Western Europe and North America as a result of prophylactic treatment and altered behavior. Some of the difference must be environmental—overcrowding, for example, contributes to the spread of tuberculosis—but how much is environmental remains a subject for research.

Developing Countries

The situation in the developing countries is very different. For many countries, precise information is lacking about both numbers of deaths and the causes of death, but estimates can be made from surveys of incidence and studies of fatality. For some others, data exist that are as good as those for the industrialized countries, with which some of the developing countries now deserve to be classified. In China, whose population constitutes nearly 30% of the total population of developing countries, the infant mortality rate per 1000 births fell from 195 in 1950 to 39 in 1985, and the expectation of life at birth increased from 40.8 years to 67.8 years—close to the median for that of the non–market economy industrialized countries. In the other developing countries, taken as a whole, infant mortality fell only from 173 to 100 per 1000 births and the life expectancy increased correspondingly less, from 41.7 years to 55.7 years.

WHO has estimated the number of deaths that occurred in developing countries in one year in or around 1985 and classified them into a few broad categories of cause for three geographical groupings.[1] In Table 7, the results are compared with similar data for the industrialized countries as a whole (market and non-market economies combined). Nearly 40 million of the 50 million or so deaths that were estimated to have occurred in a year in the whole world were in the developing countries. The biggest absolute and relative differences (other than the relative difference in deaths due to the complications of pregnancy) were in the proportion attributed to infectious and parasitic diseases and in the proportions attributed to neoplasms and to circulatory and certain

TABLE 7—Mortality by Cause as a Percentage of All Causes in Developing and Industrialized Countries, circa 1985

Cause of Death	Developing Countries: Africa and Middle East (11.5)	Developing Countries: Asia (23.2)	Developing Countries: Latin America and Caribbean (3.2)	Industrialized Countries (11.0)
Infectious and parasitic disease	60.0	39.7	28.1	4.6
Neoplasms	3.9	7.5	9.4	20.8
Circulatory and certain degenerative diseases	10.4	19.0	28.1	53.7
Chronic obstructive lung disease	1.0	9.1	2.8	3.5
Complications of pregnancy	1.8	1.1	1.1	<0.1

Injury and poisoning	4.8	6.9	7.8	7.0
Other and unknown	8.6	9.0	13.3	9.5

Note. Adapted from Lopez.[1] Numbers of deaths in millions per year are shown in parentheses.

TABLE 8—Deaths Attributed to Infectious and Parasitic Diseases in Developing Countries, circa 1985, by Age and Cause

Cause of Death	Annual Deaths (in thousands): <5 years of age	Annual Deaths (in thousands): ≥5 years of age
Diarrheal diseases	4000	1000
Tuberculosis	300	2700
Measles,[a] whooping cough, and diphtheria	2200	...
Malaria[b]	750	250
Schistosomiasis	...	200
Acute respiratory diseases	2800	2000
Other infectious and parasitic diseases	450	350
Total	10 500	6500

Note. Adapted from Lopez.[1]
[a]400 000 measles-related deaths are included under diarrheal diseases.
[b]Up to 1 million malaria-related deaths are included under other infectious and some noninfectious diseases.

degenerative diseases. The proportion of deaths attributed to infectious and parasitic diseases *dropped* progressively from a high of 60.0% in developing countries in Africa and the Middle East through somewhat lower rates in Asia and in Latin America and the Caribbean to a low of 4.7% in the industrialized countries. The proportions of deaths attributed to neoplasms and to circulatory and some degenerative diseases *rose,* in contrast, in the same order (from 3.9% to 20.8% and from 10.4% to 53.7%, respectively).

The differences between national groups in mortality from diseases that increase in incidence with age are largely due to the different age distributions of the populations—the smallest proportion of old people is in the developing countries of Africa and the Middle East. In part, however, they also reflect differences in the patterns of disease at each age, with high incidence rates of vascular disease and neoplasms in the industrialized countries due principally to the eating, drinking, smoking, and reproductive behavior of the inhabitants.[8]

The high proportion of deaths attributed to infectious and parasitic diseases (including influenza, acute bronchitis, and pneumonia) in the developing countries falls most heavily on children younger than 5 years of age (Table 8). Over 10 million deaths a year from infectious and parasitic diseases (61% of the total) are estimated to occur in this age group; several million of these deaths are due to diseases that have been almost eliminated from the industrialized countries and entirely eliminated from some of them. The attribution of each of these deaths to a single cause (which was required for the preparation of the table) is, however, an even more arbitrary procedure than it often is for the deaths of old people in industrialized countries. Children often have multiple infections that are made severe by malnutrition and there may be little reason to choose one as the cause of death rather than another. Many of the deaths attributed to diarrheal diseases are related to measles, and up to a million deaths classified under "other infectious and parasitic diseases" and some noninfectious diseases are related to malaria. The total number of deaths due to malaria is threatening to rise above 2 million a year as chloroquine-resistant parasites spread more widely.

The deaths attributed to "other infectious and parasitic diseases" include about 25 000 attributable to poliomyelitis (80% in children younger than 5 years of age) and many thousands from amebiasis, hookworm, hepatitis B (excluding the complication of liver cancer), and acquired immunodeficiency syndrome (AIDS). A further 800 000 deaths attributed to neonatal tetanus, practically all of which occur in the developing countries, are not included in the figures for infectious disease, as they are classified under perinatal deaths.

This high mortality in developing countries, serious though it is, is lower than it was at the beginning of the century and there is no lack of knowledge to prevent it being reduced almost to the level in the industrialized world. The causes of the current excess of ill health in the developing world are for the most part environmental in origin, in the broad sense of the term, and are essentially avoidable. Head and shoulders above the rest is poverty—poverty of the individual that results in malnutrition and lack of shelter, and poverty of the state that makes it difficult to provide adequate standards of education and immunization and to provide the classical public health measures that were introduced into the industrialized countries before, or shortly after, the beginning of the century. These measures are difficult, but not impossible, to provide, as was demonstrated in China in the 20 years that followed the start of the Communist regime, when a dictatorial and bureaucratic system of social organization was able to ensure that central directives were effectively carried out, agricultural production was improved, food was more evenly distributed, an immunization program was fulfilled, and fatal childhood infections were greatly reduced.

Other environmental hazards that affect primarily adults include many that were characteristic of the industrialized world during its period of development. Occupational hazards, like that from asbestos, and general atmospheric pollution with smoke from the industrial use of coal

are often poorly controlled. More important, because it is more widespread and affects a larger proportion of the population, is the indoor pollution from the use of biomass fuels for cooking and heating in small rooms with inadequate ventilation that is prevalent in north China and parts of India. This indoor pollution may be partly responsible for the high proportion of deaths (9.1%) attributed to chronic obstructive lung disease in developing countries in Asia. It may also be partly responsible for the relatively high incidence of lung cancer in women in north China, many of whom spend much of their day in such confined and polluted spaces. Further research is needed to establish the relative importance of indoor pollution and the extent of its interaction with tobacco use and other factors.

The Interdependence of Health in All Countries

Considered sui generis, none of the facts I have described justifies my initial statement that the activities in each part of the world affect conditions everywhere else and that we need to examine what is happening in other countries when we examine the relationship between health and the environment in our own. I could have cited the spread of AIDS in Africa as an example, had I not specifically excluded the risk of AIDS from consideration by excluding from environmental factors those that individuals can largely choose to avoid. What I had in mind, however, was the much more complex effect of human activities on the world's climate and resources.

Climatic Change

Until recently any suggestion that human activity could have global effects would have been dismissed as science fiction. Now, however, two effects of human activity have been confidently predicted: an increase in the amount of shortwave ultraviolet radiation reaching the earth and an increase in global temperature.

The first effect is produced by the dispersal into the atmosphere of chlorofluorocarbons from aerosol sprays, plastic foam blowers, and refrigerants, and of halons from fire extinguishers. These gases, which have been produced only since the end of the Second World War, can persist in the atmosphere for up to 100 years, and their concentration in the atmosphere increased during the 1980s by about 5% per year. Chemically they interact with ozone; they are depleting the ozone layer over the mid-latitudes in the northern hemisphere by 4% to 5% per decade and the global ozone layer by 2% to 3% per decade.[17] Much greater depletion must be expected, even if the United Nations agreement signed by 93 countries in June 1990 is adhered to: namely, to stop producing chlorofluorocarbons by the end of the decade and to provide a fund of $240 million to help developing countries obtain alternatives.

The direct effect on health of this global change may be relatively small—an increase in the risk of melanomas and of basal and squamous cell carcinomas of the skin by perhaps 20% to 30%, which could be avoided by changes in personal behavior. Much greater effects may be produced indirectly through damage to phytoplankton in the oceans and other critical organisms in the food chain.

The second effect is more long-term, more potentially damaging, and much more difficult to prevent. It arises from the progressive accumulation of "greenhouse gases" in the atmosphere (principally carbon dioxide, methane, and nitrous oxide; carbon dioxide is responsible for half the effect) and is thought likely to increase mean global temperatures by 1.0°C within 30 years and 3.0°C by the end of the next century. Such a change would be almost as big as the fall of 4°C that occurred in the last ice age. A change of this order would be expected to reduce the cover of snow and ice in the Arctic and Antarctic and to cause a rise in sea level of around 20 cm in the next 40 years and around 65 cm by the end of the century, a general redistribution of weather patterns, and drastic local changes in the distribution of rain. There are many uncertainties that make precise prediction impossible. Again, the direct effect of these changes on health may be small, but the indirect effects could be substantial; such indirect effects might include the aggravation of food shortages, the extension of areas favorable to parasitic disease, and a vast increase in migration. Reversal of such effects would take many generations; the time to prevent them is now. Prevention would entail increasing the tree cover of the globe (to increase the removal of carbon dioxide) and reducing the combustion of fossil and biomass fuels, whereas the reality is that the reverse is certain to happen for many decades to come, due to the inexorable increase in the world population and the need for developing countries to increase their productivity if they are to raise their standards of health to that of the industrialized world.

Impact of Population Growth

The estimated world population in 1800 was about 1 billion, in 1900 about 2 billion, and in 1987 about 5 billion. The world population is still increasing at the rate of about 26 persons every 10 seconds. The increase, of course, is due to the fact that mortality rates are falling faster than fertility, and unless fertility falls much faster in the future than it now appears likely to do, the population is expected to reach about 8.2 billion in 2025 and perhaps 10 to 12 billion before it eventually stabilizes.

Whether agricultural production can increase sufficiently to provide a reasonable diet for so many people is seriously in doubt. Up to now better agricultural practices, the greater use of fertilizers, and the introduction of new varieties have enabled standards to rise in many countries despite an increasing population, but the productive capacity of the earth is limited. Myers[18] has calculated that even if we all ate a vegetarian diet and shared our food equally the biosphere could not support more than about 6 billion people; if everyone were to require 35% of their calories to come from animal products, as is now the case in North America, the biosphere could adequately support only about half its present population.

In practice, the biosphere is not being farmed ideally. Not enough food is distributed from areas where it is overproduced to areas where it is needed. Where industrial production has not developed to a level that enables the country to buy food, malnutrition is widespread, and the overuse of marginal soils in some of the poorest areas is causing progressive desertification, with a consequent reduction in the potential for food production in the future.

By far the largest increase in population is taking place in the developing countries, and this is likely to remain true for many years to come. Table 9 shows the population of the industrialized and developing countries in 1950, the percentage increases in both groups between 1950 and 1985, and the expected increases by 2025. Both the number and the proportion of people who will require an increased standard of living, if their standard of health is to be raised to a level that would be regarded as acceptable in our own countries, is increasing steadily. If past experience is anything to go by, such an

TABLE 9—Predicted Growth of World Population, 1990 to 2025

Type of Country	1990 Population (millions)	Percentage change since 1990	
		1995	2025
Industrialized	832	+41	+68
Developing	1684	+118	+304

Note: Adapted from the Report of the WHO Commission on Health and the Environment, Geneva: World Health Organization, 1992.

improvement cannot be achieved without either dictatorial imposition of behavior or a greatly increased use of biomass and fossil fuels, with a corresponding increase in the production of carbon dioxide. Moreover, the increasing population will require more land for agricultural purposes and more wood for fuel. Consequently, the rate of destruction of tropical rainforests—which are at present being reduced by about a hectare every 20 seconds—will be accelerated, thus reducing the ability of the biosphere to remove carbon dioxide and speeding further the processes that lead to uncontrollable climatic change.

Conclusion

The environmental factors that I have reviewed form only one component of the many factors that are shaping the health of the peoples of the world, and I do not wish to give the impression that others are unimportant. On the contrary, the outlook for health in Great Britain and the United States in the immediate future is highly encouraging (apart from the increasing risk of AIDS) principally because of the possibility of reducing the risk of premature death in middle age by reducing the prevalence of smoking, modifying diet, and improving treatment. In some developing countries one of the urgent tasks is to prevent the spread of the epidemic of smoking that the tobacco industry is striving to cause. If even the present smoking habits of young people are continued into later life, tobacco can be expected to cause 10 million deaths a year worldwide by the 2020s.[19]

Environmental factors, nevertheless, continue to be immensely important in both industrial and developing countries—although not primarily the factors that are often singled out for special emphasis. That modern industry has given rise to many occupational hazards and to the dispersal of small amounts of many potentially toxic chemicals is not open to question. In Great Britain and the United States, however, both are now tightly controlled, and public exposure to them has been so small that any associated risk is difficult if not impossible to detect. The major environmental hazards that now need to be tackled are quite different: poverty, the pressure of population growth, and the production of greenhouse gases.

Poverty is immensely difficult to deal with and I know no easy solution. In the United States a beginning could perhaps be made, on a pilot basis, by redistributing the $4 billion currently spent each year by Superfund on cleaning up waste sites that, according to the National Research Council's committee,[10] have been selected on the basis of engineering feasibility rather than on degree of hazard. The money could be used to improve conditions in selected poverty-stricken areas. To make effective use of the funds, however, according to WHO's Commission on Environment and Health,[20] it would be essential to involve the local population in decisions about their use.

In developing countries the greatest contribution that biomedical science can make is to help reduce the pressure of population growth. Fertility rates fall as economic and educational standards rise and mortality is reduced, but the world, and developing countries in particular, cannot wait for this to happen. The demands placed on resources by the growing population and growing consumption are too severe. Wealthy countries, for their part, can contribute to worldwide population reduction in two ways. First, they can reduce their fertility rates to reproduction level or below (as has already been done in the United States and Great Britain), not only to set an example, but also because their citizens make the biggest demands on limited resources. The citizens of the industrialized nations consume about 10 times as much fossil fuel as do the citizens of developing countries, with US citizens consuming 40 to 50 times as much as the citizens of the poorer African and Asian countries. Second, the wealthy countries can provide funds for the support of family planning worldwide and for research into th development of contraceptives (both male and female) that require a minimum of medical intervention.

Lastly, and equally difficult, is the adoption of policies to reduce the production of greenhouse gases. The responsibility for this reduction is squarely on the shoulders of the countries that are already industrialized, for the developing countries cannot be expected to refrain from increasing their production at least to the level required to enable them to have the standard of health to which we are accustomed in North America and Europe. No one method will secure the necessary result, but it can be achieved by the combination of several methods. We must achieve greater efficiency in the use of energy by insulating to avoid heat loss and by substituting public for private transport, and we must decrease our reliance on fossil fuels, possibly by making greater use of nuclear power and certainly by developing methods for obtaining energy from renewable sources (winds, tides, and sun).

The achievement of these aims is essentially a political problem, but that is no reason for us not to be concerned with it. By increasing our life spans and raising our standard of living, medicine and industrial development have indirectly created the problems resulting from our higher consumption of natural resources, and we cannot escape partial responsibility for them. □

Commentary: Environmental Disease—A Preventable Epidemic

ABSTRACT

Toxic environmental diseases are highly preventable causes of morbidity and mortality. Toxic diseases in the work environment cause an estimated 50 000 to 70 000 deaths and 350 000 new cases of illness each year in the United States; the asbestos pandemic will ultimately claim at least 300 000 lives; pediatric lead poisoning is epidemic, and an estimated 3 to 4 million US preschool children have blood lead levels above 10 μg/dl and could suffer long-term neuropsychological impairment. Prevention of environmental diseases can be achieved through legislation and regulation that control common-source exposures to chemical toxins. Modification of personal behaviors, such as tobacco and alcohol consumption, complements but does not replace control of toxic environmental exposures. (*Am J Public Health.* 1992;82: 941–943)

Philip J. Landrigan, MD, MSc

Introduction

Disease caused by toxic chemicals in the environment is a substantial yet highly preventable cause of morbidity and mortality in the United States and around the world. Consider:

• *Lead poisoning.* Lead poisoning is epidemic among young US children. The Centers for Disease Control (CDC) estimates that 3 to 4 million American preschool children have blood lead levels above 10 μg/dl.[1] Blood lead levels in this range in young children have been shown to cause depression of neurological and psychological function,[2–4] effects that appear to be permanent.

• *Asbestos.* Asbestos in the work environment has created an absolute disaster.[5] Although the hazards of asbestos were known in the 1930s, billions of tons of asbestos were used in the United States from then until the 1980s. Millions of workers were exposed, and tens of thousands of homes, schools, and other public buildings were contaminated.[6] By the year 2000, an estimated 300 000 American workers will have died of the diseases caused by asbestos: principally, asbestosis, lung cancer, and malignant mesothelioma. It is anticipated that deaths will continue to occur well into the 21st century.[7] With the overseas spread of asbestos-containing building materials, the pandemic is now extending to the Third World.

• *Occupational disease.* Studies conducted in New York State have estimated that 50 000 to 70 000 US workers die each year of chronic occupational disease resulting from past exposures to toxic substances.[8] These diseases encompass a broad range: besides the lung cancer and mesothelioma of asbestos workers,[5] they include cancer of the bladder in dye workers[9]; leukemia and lymphoma in workers exposed to benzene[10] and ionizing radiation[11]; chronic bronchitis in workers exposed to dusts[12]; disorders of the nervous system (including possibly dementia, Parkinson's disease, and motoneuron disease) in workers exposed to pesticides, solvents, and certain other neurotoxins[13]; renal failure in workers exposed to lead[14]; and cardiovascular disease in workers exposed to carbon monoxide[15] and carbon disulfide.[16]

A major impediment to assessing the contribution of synthetic chemicals to the causation of cancer and other workplace diseases is the fact that only 20% of the

The Potential Impact of Epidemiology on the Prevention of Occupational Disease

David H. Wegman, MD, MS

ABSTRACT

This presentation reviews occupational epidemiology as a foundation for workplace disease prevention activities. By examining descriptive, etiologic and intervention occupational epidemiology studies, a range of opportunities are illustrated where epidemiology has played, or could play a principal role in guiding preventive efforts. Descriptive studies presented include ones based on vital records, on epidemic investigations, cross-sectional surveys, and surveillance. Etiologic studies review the largely successful development of knowledge for lung cancer and asbestos exposure for pulmonary effects of isocyanate exposures. However, attention is also directed to the need for etiologic studies of work environment risks for both cardiovascular and musculoskeletal disease. Finally importance is placed on the too infrequent epidemiologic studies of intervention. Historical examples of control of large risks from nickel cancers and silicosis are balanced with more recent examples of successes at reducing smaller risks of cardiovascular disease and oil acne. Throughout, emphasis is placed on the importance of reintegrating the academic discipline of epidemiology into the application of study findings to prevention of workplace risks. (*Am J Public Health.* 1992;82:944–954)

Introduction

Over the first half of this century public health professionals used the tools of epidemiology primarily for the prevention of infectious disease. The appropriate knowledge was gained in the standard public health curriculum and communication between academic and practicing epidemiologists was relatively easy. Much of the epidemiologic research of that time was carried out by professionals who served as or closely collaborated with public health epidemiologists in studying both the cause and the prevention of epidemics.

More recently, however, as attention has shifted to the study and prevention of noninfectious disease, a gap has appeared between the contemporary discipline of epidemiology and the practice of public health. Szklo[1] suggested that this gap relates to a generational difference in epidemiologists, "a difference expressed by the fact that those who produce data needed for preventive programs (namely epidemiologists) and those in charge of carrying out such programs very often are not, unlike in the good old days, the same people at all."

These comments reflect the fact that epidemiologic study in the United States has come to focus most often on well-planned, large, time-consuming studies of chronic disease. Such studies have benefited from the development of new methodology but also have required less direct interaction with public health agency personnel and use of public records. As a result, as the tools of epidemiology have become more powerful and the scientific base of the discipline has broadened, epidemiologists have turned more and more to the excitement associated with seeking new knowledge and left to others the more mundane task of implementing that knowledge.

The evolution of epidemiologic methods in studying noninfectious disease has been of particular benefit to the study of occupational disease and has resulted in expanded knowledge about health risks in the work environment. Consequently, many bright young scientists have been attracted into the discipline. The positive developments in epidemiology as an academic discipline, however, have been accompanied by increasing distance between the development of and the practical application of new knowledge. Consequently, this commentary is directed at rebuilding bridges between academia and public health agencies, over distances that, I believe, are short and through terrain that is exciting.

In exploring applications of epidemiology to the prevention of occupational disease, it is useful to examine potential opportunities according to the recognized study categories: descriptive, etiologic, and intervention. The first two of these are commonly considered, but there is an unusual opportunity to emphasize the third when undertaking occupational epidemiology studies.[2] *Descriptive studies* provide information for setting priorities, identifying hazards, and formulating hypotheses for new occupational risk. It is surprising how often such studies have

proved sufficient to initiate intervention. *Etiologic studies* are planned examinations of causality and the natural history of disease. These studies have required increasingly sophisticated analytic methods as the importance of low-level exposures are explored and greater refinement in exposure-effect relationships is sought. Finally, *intervention studies* seek to demonstrate that steps taken to reduce work-related risk factors do, in fact, result in measurable disease reduction or improvement in the health of the work force.

Much of the emphasis in modern epidemiology has been on studies of etiology. These, of course, need to remain prominent, but not to the exclusion of the other essential roles for epidemiology. The following examination of accomplishments in each of the three areas, therefore, is designed to kindle an enthusiasm and sense of activism for the full range of opportunities to use epidemiology in the prevention of occupational disease.

Descriptive Epidemiology

William Farr offered one of the earliest systematic applications of epidemiologic descriptive analyses to occupational risks. He took advantage of Great Britain's vital records reports on occupation-related mortality to illustrate the striking mortality excesses among metal miners.[3] Using the data shown in Table 1, he demonstrated that the metal miners of Cornwall experienced higher mortality from all causes than did the general population. To examine whether the excesses were in some way due simply to underground work, he compared metal miners with coal miners. He concluded that mining alone did not provide a sufficient explanation of the excess risk.

After examining cause-specific mortality Farr was able to show that the excess was concentrated in deaths from pulmonary disease. Table 2 illustrates the results of his efforts to examine whether the excess was unique to Cornish metal miners. Pulmonary disease mortality in lead miners from two other parts of Great Britain (Northern counties and Wales) was compared with that of the Cornish miners. Despite some regional differences, it is reasonable to conclude that the excesses in the Cornish and other miner cohorts were due to the metal mining itself. An interesting historical note is that, at this early date, Farr introduced healthy worker selection as an explanation for the pulmonary disease mortality findings among the youngest miners in the two comparison regions.

TABLE 1—Average Annual Deaths per 1000 from All Causes: Cornwall Metal Miners Compared with All Other Cornwall Deaths and Northern Coal Miners

Age Range	Cornwall Metal Miners Mortality Rates (1860–62)	Rate Ratios: Metal Miners/General Population	Rate Ratios: Metal Miners/Coal Miners
15–25	8.90	1.25	1.06
25–35	8.96	1.01	1.06
35–45	14.30	1.43	1.41
45–55	33.51	2.27	1.99
55–65	63.17	2.63	2.58
65–75	111.23	1.89	1.71

Note. Adapted from Farr.[3]

TABLE 2—Ratio of Pulmonary Disease Mortality Rates in Metal Miners Compared with All Other Residents in Three Regions

Age Range	Cornwall Metal Miners	Welsh Lead Miners	Northern Lead Miners
15–25	1.14	0.89	0.88
25–35	1.06	0.72	1.24
35–45	1.86	1.96	3.34
45–55	4.55	2.08	4.45
55–65	8.34	2.89	5.75
65–75	4.30	2.85	3.06

Note. Adapted from Farr.[3]

The high prevalence of employment in one major type of work and the high prevalence of disease due to that work provided Farr a rich soil to till. Data of this type are not as likely to provide such dramatic findings today. However, the existing decennial publications from Great Britain and the occasional reports from other geographic locations provide a valuable resource on mortality experience for different occupational groups that, as yet, are incompletely explored for hypotheses about work-related risks.[4]

Descriptive studies of illness outbreaks can also be seen to play a role in prevention. This fact is illustrated by an outbreak investigation that was initiated by a report from a hospital clinic. Eleven employees from a nearby polyurethane production plant visited the clinic, all with symptoms of urinary retention. A review of the medical records of these workers found no common diagnosis and so a survey of the entire work force (208 employees) was planned.

An appropriate case for study was arbitrarily defined as the report of at least two of four specific urinary tract symptoms. Sixty-three percent of the production workers met the case definition. A plot of onset times (Figure 1) showed strikingly how the outbreak coincided with the introduction of a new chemical catalyst. This observation formed the basis of a recommendation that the catalyst be replaced. It can be seen that the outbreak abruptly ceased after the catalyst was removed. This and a parallel epidemic investigation in another city led the producer to remove the catalyst from commercial use. Publication of the findings[5] also led to a collaboration with toxicologists who are now studying the biochemical mechanism of the toxic action and also exploring the potential neurotoxicity of related compounds.[6–8]

Similar occupational disease outbreak investigations provide lessons about the growth of knowledge about occupational disease and the opportunities for its prevention. Other sources of descriptive knowledge are also documented, including reports based on such simple but elegant insights as relating disease in the community to the correct denominators. For example, Aksoy reported an evaluation that was based on 26 acute leukemia

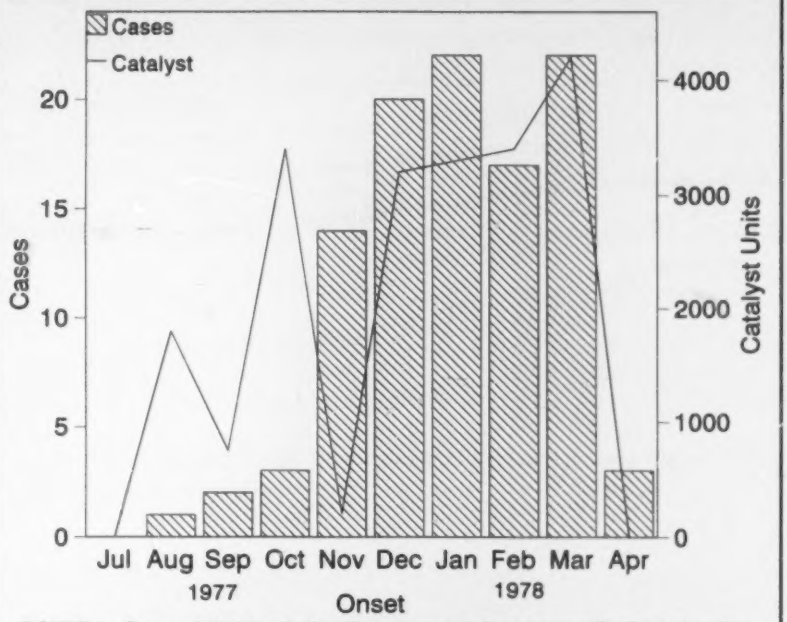

FIGURE 1—Cases of bladder dysfunction among workers by month of onset and by amount of catalyst used. Adapted with permission from Kreiss et al.,[5] Copyright © 1980, American Medical Association.

TABLE 3—Percentage of Workplaces in which Environmental Hazards Were Found, by Size of Workplaces (Thailand Workplace Survey)

Hazard Type	Workplace Size: Less than 50	Workplace Size: 51–150
Lead fumes/vapors	20	15
Airborne irritants	46	52
Heat stress	30	33
Excessive noise	50	20
Inadequate lighting	54	30
Accident potential	66	50

Note. Adapted from El Batawi and Husbumrer.[11]

cases that were among those newly diagnosed in Istanbul over a 7-year period. He observed that these 26 cases occurred in shoe industry workers, whereupon he used census data to estimate that a total of 28 500 workers were employed in Istanbul's shoe industry. Using a quasi–person-years approach, he then calculated a 7-year crude incidence rate for leukemia of 13 per 100 000 among shoe industry workers, which could then be compared to the estimated 6 per 100 000 in the general population of Istanbul.[9] Aksoy hypothesized that the difference in risk was due to exposure to benzene contained in the glues used in the shoe industry, which included many small workshops and few exposure controls.

Although this descriptive analysis has been criticized for a number of limitations, the hypothesis of benzene-related leukemia has since been confirmed. Furthermore, at least two important public health consequences can be traced to this simple descriptive study. First, the hypothesis presented in this study served to stimulate several well-planned etiologic studies, results from which were used to guide reduction in established exposure limits.[10] Second, an increase was seen in the pace of voluntary substitution or control of benzene even as the hypothesis was being tested.

Well-planned, descriptive field surveys can also provide important guidance for targeting more general prevention activities. In Thailand, a stratified sample of different types of small and medium manufacturing firms identified a need for a variety of occupational health services.[11] In addition to the wide distribution of hazards shown in Table 3, the survey provided evidence that over a third of printing and battery workers had some symptoms or signs of lead poisoning and a disproportionate number (almost 50%) of textile workers suffered from upper respiratory infections. The survey led the Health Ministry to direct new attention to workers' health with development of educational programs for workers and professionals, establishment of a new occupational hygiene laboratory, and passage of legislation to require more health care for small industries.

Finally, another form of descriptive epidemiology worthy of mention is surveillance. Surveillance continues to play a central role in the identification and control of communicable diseases. It has not so far proved as valuable when applied to occupational disease, although as far back as William Farr there are examples of moderately successful forms of surveillance.

An example is provided from the annual US occupational injury reports. Generally these reports have attracted little attention, but there is intense interest in determining the cause of the recent striking rise in reports of repetitive trauma disorders in the United States.[12] Between 1972 and 1982 the number of reports of such disorders was close to 20 000 per year. Since 1983, however, there has been a steady rise in reports, and the number is now over three times higher. Initial examination of these trends suggests that they cannot be explained by increased reporting alone but are likely to represent a real increase in disease incidence as well.

New approaches to occupational disease surveillance are being explored.[13] But in the spirit of a broader concept of occupational epidemiology, I would like to call attention to a less familiar form of surveillance, hazard surveillance. Hazard surveillance is directed at work exposures rather than disease, but is consistent with MacMahon and Pugh's definition that epidemiology is the study of the "distribution and determinants of disease."[14] A major benefit of hazard surveillance is that it should provide more timely information on risks related to agents that cause chronic long latency disease such as mesothelioma.[15] In contrast to the mesothelioma registry, hazard surveillance of asbestos exposures could show trends predictive of future disease without waiting to count the actual cases. Surveillance of exposure trends can be seen as following trends in disease *risk,* rather than in disease itself.

The potential for hazard surveillance can be illustrated with information from the US Occupational Safety and Health Administration (OSHA) compliance activity. A detailed analysis of lead exposures collected over the decade following the introduction of a new lead standard

(Table 4) shows that problems persist in the six major lead industries that were the focus of the standard.[16] Not shown is the fact that, despite issuance of the new standard in 1978, there is no trend toward lower exposures.

Detailed review of job-specific exposures called attention to several specific jobs in which overexposure was most serious. A particularly important and unexpected finding emerged from the analysis of exposures *outside* the six major industries. Excessive lead exposures in the job title "painter" appear in a number of different industry groups. Although structural painters have long been known to risk lead exposure, these data showed that small numbers of painters in a wide variety of industries commonly had elevated lead exposures. Among the 848 inspections of plants that were not part of a lead industry, one third of the test samples exceeded the exposure limit, 39% involving this one job title. These results from epidemiologic surveillance of hazards characterized the need for a program targeted to this hidden generic problem.

TABLE 4—Inspections in which Observed Levels Exceeded Permissible Exposure Levels (PELs) and Samples in which Levels Exceeded Permissible Levels: OSHA Inspection Data, 1979–1985

Industry	No. (%) of Inspections with Median Levels > PEL	No. (%) of Samples with Levels > PEL
Inorganic pigments	25 (52)	143 (60)
Primary lead	5 (40)	72 (83)
Secondary nonferrous metals	86 (43)	718 (49)
Brass/bronze/copper foundaries	118 (42)	822 (44)
Storage batteries	87 (57)	969 (56)
Primary batteries (dry and wet)	18 (33)	180 (38)

Etiologic Epidemiology

Doll has suggested that to indicate etiology, epidemiologic studies should meet at least four requirements. They should show (1) positive associations between exposure and disease in populations with known exposure; (2) associations shown not to be due to bias, confounding, or chance; (3) associations that are replicated in different circumstances; and (4) associations that vary appropriately with dose and period of exposure.[17] He argues, however, that the International Agency for Research on Cancer requirement for the association also to be strong is inappropriate for public health because that requirement is likely to emphasize only large but rare risks. In the context of prevention, epidemiologic studies of etiology are most useful when they (1) improve understanding of exposure and exposure-response relationships, which provides information essential for primary prevention; and (2) advance knowledge about host factors and early markers of effects, which contributes to efforts at secondary prevention. These features will be illustrated with examples from the study of occupational cancer and from the study of occupational pulmonary disease.

The evolution of our current understanding of asbestos-related cancer illustrates the importance of epidemiologic study in developing and examining hypotheses about the nature of the risk. During the first half of the 20th century case reports and descriptive studies provided suggestive evidence that asbestos was a carcinogen. However, the first well-planned epidemiologic studies to address the question were not carried out until the mid-1950s. Then in 1954 and 1955 the suspicion that asbestos was carcinogenic, not just fibrogenic, became a specific hypothesis after the almost simultaneous publication of Doll's cohort study of asbestos textile workers[18] and Breslow's case-control study of lung cancer.[19] Doll's study documented an 11-fold excess risk in textile workers, while Breslow's study provided evidence that asbestos-related lung cancer mortality was not due to cigarette smoking alone.

The following quarter-century saw probably the most intensive effort at epidemiologic investigation directed at any work environment risk to date. When such efforts were summarized by McDonald in 1987, a total of 50 cohort studies of men and women had been carried out.[20] A number of different findings useful for prevention emerged from these studies. The characterization of cumulative exposure and lung cancer risk has now been provided for several different industry groups. For example, Dement showed convincing evidence of the high risk associated with chrysotile exposures in textile work,[21] and McDonald provided equally convincing evidence that workers exposed during mining of the same material were at much lower risk.[22] McDonald has illustrated this (Figure 2) by applying uniform calculations of relative risk to several different cohorts.[23]

A separate finding from several other studies has been that the components of cumulative exposure (duration and intensity) have been shown to contribute independently to risk. This was demonstrated even when intensity could be categorized only as light, moderate, and severe,[24] as well as when average dust categories could be estimated.[25] A third lesson from studies of asbestos and lung cancer derives from one of the strengths of large cohort studies, the opportunity to examine small risk differences. In several asbestos cohorts it has been possible to document the effects of asbestos independent of cigarette smoking and in at least one the risk was shown to be more than additive.[26]

Thus, epidemiology studies have contributed importantly to providing answers to a great number of questions about asbestos risk. Severe restrictions have now been adopted to control use or exposures in most developed nations. Still, interesting questions remain. Some, such as why different fiber types are associated with different magnitudes of risk, will probably benefit more from experimental studies than from further epidemiologic study. Others, however, are probably well suited to an epidemiologic approach—for example, whether exposure level alone or other cofactors are the most likely explanation for the striking risk differences for chrysotile when exposure occurs in textile factories in contrast to exposure in mining, milling, or the manufacture of friction products.

The epidemiologic study of an occupational cancer risk provides important evidence to guide primary prevention activity. However, when it comes to cancer there are few tools available to the epidemiologist that allow much of a contribution to knowledge useful for secondary prevention. This is not the case for respiratory disease, as can be illustrated by the contribution of epidemiology to studying isocyanate-related acute pulmonary disease.

In 1951, case reports of isocyanate-related pulmonary effects called attention to a new cause of occupational asthma.[27] Early epidemiologic studies were not able to add much to the case reports because those with asthma often left the work environment. Then, in the late 1960s, Peters and his colleagues initiated studies of workers exposed to very low levels of isocyanates. In very low exposures, few cases of asthma and thus little healthy worker selection bias were anticipated. Moreover, Peters et al. took advantage of the ease of field measurement of pulmonary function to test workers frequently over a work week both before and after their work shifts. In this way they were able to identify evidence for short-lived reactions to environmental exposures.

Significant changes in 1-second forced expiratory volumes (FEV_1) over the work shift were demonstrated (Table 5), as well as the fact that acute changes were more striking in those who had ever smoked cigarettes.[28] A 3-year prospective study of the same workers demonstrated that the losses were not just acute; exposed workers experienced accelerated losses over 3 years and there appeared to be a correlation between the magnitude of cross–work shift change and the accelerated functional loss.[29,30] The findings suggested that isocyanates were not only asthmagens but also caused nonspecific bronchoconstriction. It was further suggested that those most likely to suffer accelerated loss in lung function could be identified by cross-shift measurements of pulmonary function. Further studies supplemented these findings with evidence for the relationship of chronic function losses to exposure level (Table 6).[31,32]

Peters et al.'s work was elegant in its simplicity and clarity. It also provided evidence that cross-shift change in pulmonary function could be used both as a measure of outcome for epidemiologic studies and, potentially, for medical monitoring as well. Peters et al.'s study may have underestimated the importance of isocyanates because it was, as is often the case, a study of current employees—that is, a survivor population. Weill and his colleagues had an unusual opportunity to undertake a prospective study of employees who were exposed for the first time in a new production process. He used an approach similar to that used by Peters et al. and was able to document dose-related effects of chronic isocyanate exposure while directly accounting for healthy worker selection.[33,34]

These epidemiologic studies provided sufficient evidence that isocyanates were not only a problem for a small population of sensitized workers, but that the agents presented some risk for all exposed workers. Control efforts, therefore, could not simply be directed at the protection of a small subset of those exposed. The studies also suggest the value of the cross-shift measurement of pulmonary function and the assessment of accelerated loss of function over time as effective measures for monitoring and surveillance of exposed

populations. These add importantly to the tools necessary for both primary and secondary prevention efforts.

It is not accidental that these two examples of etiologic epidemiology come from studies of cancer and respiratory disease; these diseases have been given the greatest attention by epidemiologists. It is worth briefly examining two other very common disease groups that have not received adequate study by occupational epidemiologists: cardiovascular disease and musculoskeletal disease. If important work-related risk factors were well characterized for either of these disease groups, such factors would likely be more susceptible to preventive interventions than are the personal risk factors now known.

Cardiovascular disease is recognized as the leading cause of death in industrialized nations and is equally important in many developing nations. Through epidemiologic studies of general populations, a number of risk factors useful for prevention have been identified. A recent review calls attention, however, to important nonchemical risk factors for cardiovascular disease and concludes that there are several attractive hypotheses needing immediate attention by occupational epidemiologic study.[35]

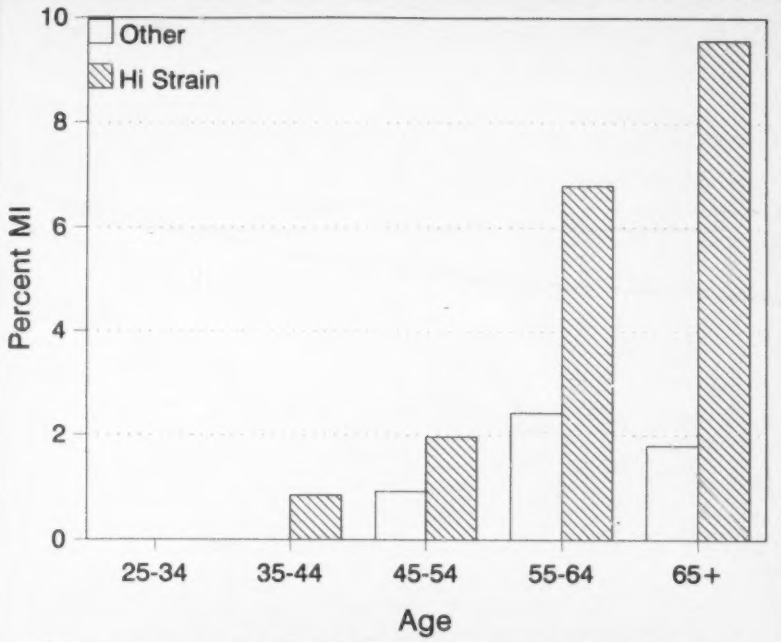

FIGURE 3—Prevalence of myocardial infarction by age and job strain (high job strain applies to those jobs judged to have high psychological demand and low worker control) among employed males surveyed in Cycle 1 of the US National Health and Nutrition Examination Survey (NHANES). Adapted with permission from Karasek et al.,[36] Copyright © 1988, American Public Health Association.

One of the possibly most important risk factors (or complex of factors) concerns the organization of work. A leading idea used in examining this risk factor is Karasek's concept of work strain. Karasek et al. have successfully captured work strain with a two-dimensional job rating scheme (psychological demands on the worker and control over those demands). An illustration (Figure 3) of Karasek et al.'s work on high strain is seen in an analysis of data from one of the US National Health and Nutrition Examination Surveys.[36] Kristensen reviewed several Scandinavian epidemiologic studies, using the two dimensions to define high strain, and concluded that there is convincing epidemiologic evidence that cardiovascular disease is associated with jobs in which there is high psychological demand matched with low worker control of the demand.[37] This effect has been noted in the Framingham Heart Disease study as well.[38] Epidemiologic studies have also begun to examine other characteristics of work organization that may be equally important, such as job instability (e.g., Siegrist[39]) and shift work (e.g., Knutsson[40]).

A second inadequately studied risk factor is the role of physical inactivity present in the work environment. This factor is particularly important because it appears that the evolution of many jobs is toward increasingly more sedentary work. In this regard, Paffenbarger and his colleagues have contributed considerably to measuring the importance of inactivity. In one of their studies of longshoremen, Paffenbarger et al. noted that those whose jobs called for high physical activity showed low risk of sudden death.[41] The total energy expenditure of the longshoremen during the workday was of the order required by other physically demanding jobs, such as a tire builder in the manufacture of rubber tires. What was especially interesting, however, was the pattern of work that appeared to be protective against sudden death. Paffenbarger et al.'s work suggested that it was not just the level of activity but the intermittent peak energy expenditure that was protective. Further epidemiologic study of this finding may be instructive for designing jobs that require intense physical exertion so that the jobs provide the maximum preventive health benefit.

If epidemiologic studies of work organization and heart disease identify features of work that can be altered, the public health impact could indeed be great. Equally important, business leaders are likely to be willing to act on such findings. The payoff of such cardiovascular disease research could be very big. If the evidence is convincing, work organization can be redesigned and proper work schedules designed. In the United States and throughout the world, increasingly more attention is being directed at trying to contain the increase in costs of medical care. Throughout the world the high prevalence of cardiovascular disease and its related disability demands public health action.

It is recognized that the problems of disability associated with musculoskeletal diseases are also experienced in a wide variety of jobs, both commercial and industrial, physically demanding and largely sedentary, male- and female-dominated. One interesting research direction is the recent work in Finland directed at determining age-related musculoskeletal *capacity*. Work of this type could lead to critical data not only on the role of physically strenuous work in causing disability but also on the need to develop physiologic criteria for retirement age that address anticipated losses in musculoskeletal capacity.[42,43]

Despite increasing attention, further progress in the epidemiologic study of musculoskeletal disease has been limited

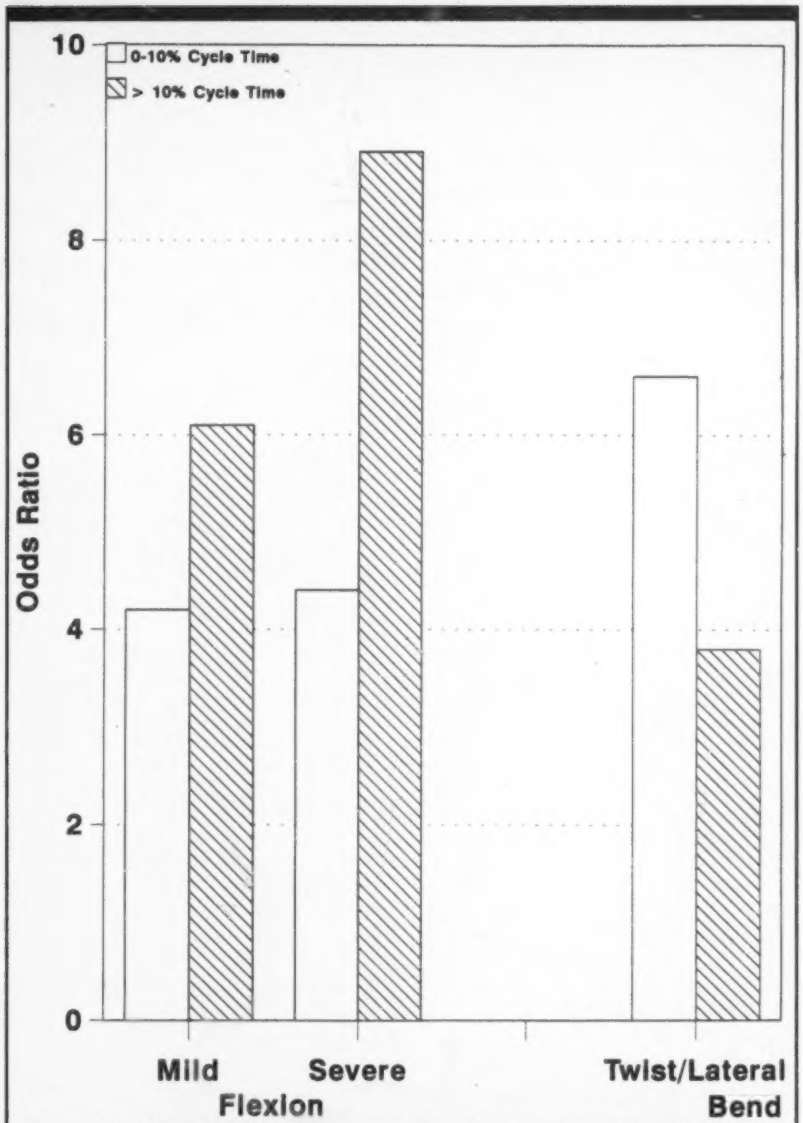

FIGURE 4—Risk of back disorders among automobile assembly workers with mild or severe use of forward flexion or with twisting and lateral bending; cycle time = time required to perform one complete set of production operations. Adapted from Punnett et al.[46]

by significant problems with proper measurement of both exposure and outcome. Recent reviews indicate that musculoskeletal diseases such as carpal tunnel syndrome[44] and different types of shoulder-neck syndrome[45] are associated with a variety of different job types. Existing knowledge of job risk factors, however, does not provide common features of these different jobs. An important priority, therefore, is to develop the means to identify and quantify relevant common microergonomic features of jobs.

An example of an initial step toward this objective is provided in Figure 4. Job-related postures were assessed by detailed videotape job analyses. Extreme and awkward postures were shown as important risk dimensions that dramatically increase risks for low back disease. In the larger group, which was studied for flexion extremes, these extremes were related to dose (as measured by cumulative time in a given posture).[46] A second example is shown in Figure 5, which presents results from a similar job analysis.[47] This analysis provided evidence that high force and high repetition are associated with increased prevalence of carpal tunnel syndrome. These findings provide hope that common job features can be identified that may prove to be important risk factors.

Objective measurements of musculoskeletal diseases also need to be greatly improved upon. Currently, careful application of precise diagnostic criteria is known to identify only the tip of the iceberg. This limitation results from the poor understanding of the pathophysiology of such conditions. Improvements will require epidemiologists to work with physiologists, kinesiologists, biomechanical engineers, and others in an effort to seek new measures of early effects and to develop test measures or validated symptom complexes that greatly increase the relevant measures of outcome.

In addition to better quantification of both exposure and outcome, more prospective studies of exposure-response relationships are required to guide intervention. For example, critical information needed for job redesign is the type and amount of change in a given risk factor required to predictably achieve a measurable or sufficient reduction in risk of disease. A vexing problem in exposure-response studies relates to the frequency and relatively short latency of many of the work-related musculoskeletal conditions. These features can result in a significant short-term turnover in the work force, which results in significant healthy worker selection effects that must be taken into account.[48]

A final issue deserves comment before I leave the subject of etiologic epidemiology. Despite all the caveats regarding proper assessment of exposure, proper use of exposure data to estimate dose, proper measures of disease, and proper attention to confounding, the results of these studies have had a profound influence on directing social activity on environmental issues. In reaction, there is also an increasing demand that the "perfect" epidemiology study be conducted before action is recommended. It is not for the epidemiologist alone to correct possibly distorted uses of and demands on epidemiology. But these developments place an important burden on each epidemiologist to take a role in proposing responsible public health action to be taken even in the face of scientific uncertainty. Epidemiologists *are* the best-equipped scientists to address the void between the knowledge that exists, the knowledge that is needed, and the public health context in which decisions must be made.[49-51]

Moreover, Sarraci notes that epidemiologic research needs to interact with the disciplines of psychology and sociol-

ogy to develop new and effective ways of communicating risk information to the different component parts of society. Furthermore, he comments, "there is a great need for the research epidemiologist to be more involved in talking and writing to people directly and indirectly through the media. In this way he would overcome his lack of training (shared with other scientists) in putting ideas over in a simple way and would contribute to the development of a soundly informed public."[52] A small step in this direction has recently been taken by in the United States by the National Institute for Occupational Safety and Health (NIOSH), which has developed a formal policy for individual worker notification concerning risks identified in NIOSH's own epidemiology studies.

Intervention Epidemiology

Studies of intervention are important as a means to evaluate hypotheses upon which intervention is based. They also should contribute to evaluating the components and determining the success of intervention programs per se, thus providing support necessary to extend or alter prevention efforts.

An early attempt to identify the impact of intervention in a work environment is provided in Doll's 1958 study, which identified a striking excess of lung and nasal cancer among nickel workers.[53] Believing that a change in industrial process by 1925 had removed the carcinogen, Doll examined time and age patterns for the cancers of interest. He noted some reduction in the excess risk with time, as well as an increase in average age at death, suggesting that there had been higher risk in the past. Unfortunately, lung and nasal sinus cancer have such a long latency that even the 1958 study could not adequately examine the effect of a change that had occurred more than 30 years before; therefore, Doll revisited the question in a follow-up study published in 1970.[54] This time (Table 7) Doll and his colleagues were able to demonstrate convincingly the essential elimination of excess risk for those first employed after the process change in 1925.

In this case, a process change fortuitously eliminated carcinogen exposure and Doll had the wisdom to examine the impact of the removal. A study from Finland on carbon disulfide and cardiovascular disease risk provides an elegant combination of etiologic epidemiology leading to intervention followed by an intervention epidemiology study. The initial evi-

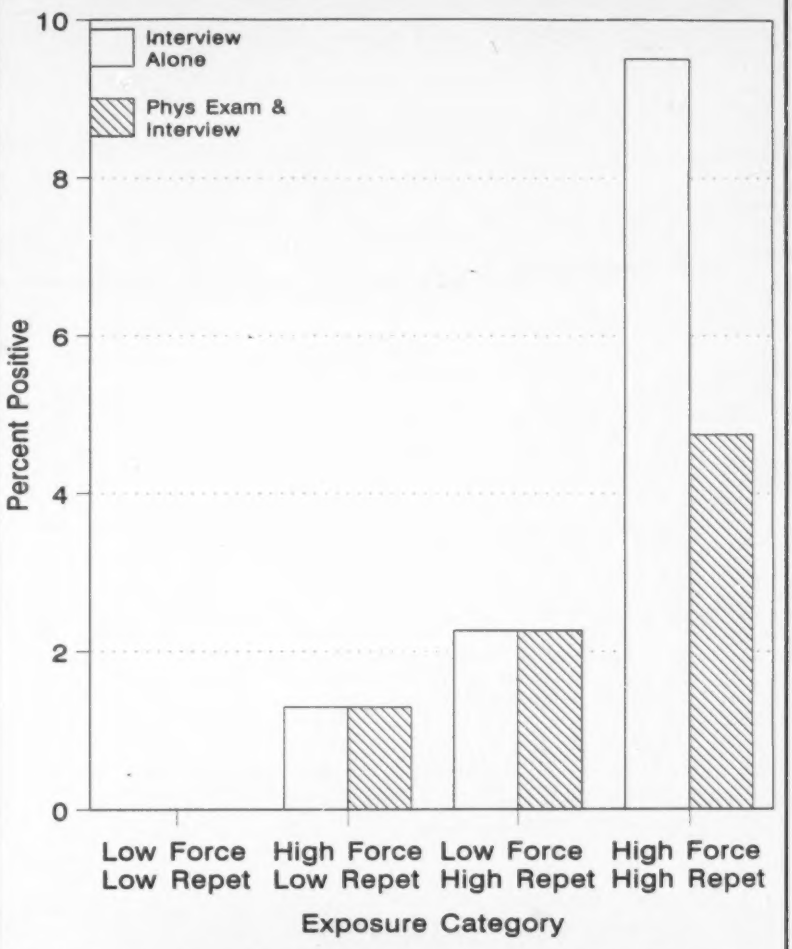

FIGURE 5—Percentage of male subjects with carpal tunnel syndrome (CTS) by force and repetition (Repet) exposure groupings. FIGURE 6—Median carbon disulfide levels (mg/m³) in air of rayon fiber factory over the 15-year interval 1965 to 1980. Control efforts were initiated prior to 1965. The exposure limit was reduced from 60 to 30 mg/m³ in 1972. Adapted with permission from Nurminen and Hernberg,[57] Copyright © 1985, *British Journal of Industrial Medicine*.

dence for the risk from carbon disulfide exposure was provided in a cross-sectional study published in 1970.[55] Because exposure control measures had been gradually improving over the years up to 1970, no new action was taken until a 5-year follow-up study demonstrated persistence of the excess risk of death from cardiovascular disease.[56] New and intensive control efforts were initiated and 10 years later a further follow-up study was undertaken. The results show dramatic evidence of risk reduction.[57] The close parallel between exposure reduction and risk reduction (Figure 6) indicates that carbon disulfide risk is reversible. The authors suggest, in fact, that the fraction of prevented or postponed cardiovascular deaths among the exposed was on the order of 70%.

Another intervention study illustrates the positive impact of control measures, although it was not designed to examine for evidence of residual risk. Excess rates of silicosis and tuberculosis were found in Vermont, where granite stonecutting is a major trade. Detailed descriptive studies in the 1930s provided dramatic evidence of work-related disease and resulted in a statewide program to assure appropriate engineering controls at all granite-cutting locations. Twenty years after the control program was started only one new (and questionable) case of silicosis had been documented.[58]

Although this was excellent evidence of the positive impact of the intervention, the study may have asked the wrong question. Fifteen years later a somewhat different question was addressed. Whereas there was no disagreement that the original goal of eliminating *cases of silicosis* had been met, a new epidemiologic study asked whether the intervention had been adequate to eliminate *all pulmonary effects* due to silica. The study examined pulmonary function in currently employed granite workers and revealed that although it was much reduced, exposure-related risk of pulmonary impairment remained. This information is of direct value in setting future intervention goals.[59]

The lung cancer and silicosis examples emphasize again the problem related to prevention efforts when the occupational disease of interest is one with a long latency. For intervention epidemiology as well as the applications discussed earlier, an effective hazard surveillance system could prove particularly valuable.

Recently hazard surveillance was used in the United States to examine the impact of a concerted effort to control silica exposures in silica flour plants. In 1980 a NIOSH investigation found that 23 of 61 employees in two plants had silica-related disease.[60] Using exposure data collected by OSHA, researchers then documented that serious overexposures were present throughout the industry.[61] This second report found that in 89% of the plants surveyed, 25% or more of the dust samples exceeded the standard. Given these findings, NIOSH issued a detailed report on engineering controls.[62] Six years later a follow-up survey of the same plants was carried out to determine the degree to which exposures had been reduced in response to the report. Unfortunately, the results indicated very limited progress that led to new initiatives.[63] This use of hazard surveillance data, however, provided timely evidence that there was a need to carry out more effective primary prevention activity without having to wait until there was evidence from a study of disease rates.

Epidemiologic studies evaluating the impact of occupational controls in industrializing nations should be particularly valuable. Scarce resources are vigorously competed for; researchers must pay special attention to documenting and understanding the use of control technology. It is not surprising, then, that applications of intervention epidemiology are available from these nations as well. For example, Lou and Zhou provided evidence of a more than 70% reduction in silicosis resulting from dust controls introduced to protect a large group of Chinese workers who were exposed to silica.[64] Another illustration of the potential value of such epidemiologic studies comes from a report on a Chinese viscose rayon plant. Evidence is provided that shows increasing production accompanied by increasing exposure levels until the introduction of a solvent recovery system resulted in the achievement of dramatic reductions in exposure.[65]

Finally, there is at least one instance in which a study was designed to examine the effects that were due to several different steps taken to control an occupational disease. The study, by Jarvholm and his colleagues, was initiated in response to the discovery of eight cases of scrotal cancer among lathe operators in a machining plant. The study was designed to review the effects of introducing a series of controls over several years.[66] Because scrotal cancer was a rare event even in this plant, oil acne cases were used as a surrogate disease outcome that was related to the same machining fluid exposures but that occurred with much higher frequency and shorter latency. The effectiveness of the

different control steps could be evaluated by tracking oil acne cases, which had been recorded since 1958. Figure 7 shows that automation (a), free clean underwear (c), and substitution with solvent-refined oils (e) appear to have been the most important control steps. The other controls show limited if any impact.

Epidemiologic studies of intervention efforts are, in principle, no more complicated than those designed for etiology. The lack of a large body of experience to consult makes the task more difficult, but not because the tools are not available. One common impediment appears to be that those responsible for interventions lack the commitment or interest to evaluate whether the intervention is successful. In trying to understand this situation I found Freyman's[67] comments on prevention instructive:

> . . . the ideal result of preventive measures is, in a clinical sense, *zero:* the complete absence of disease. To an activist by nature and education, prevention is dull. It lacks the excitement and satisfaction of discovering pathology and working for a cure. This is reinforced by our custom (in the U.S.) of paying only for performance of a measurable act and placing no dollar value on preventive services rendered to individuals.

In contrast to this characterization of prevention, apt though it may be, I hope I have shown not only that the impact of prevention activities can be exciting, but that it is the missing ingredient in the text of those who would preach prevention and expect to create converts.

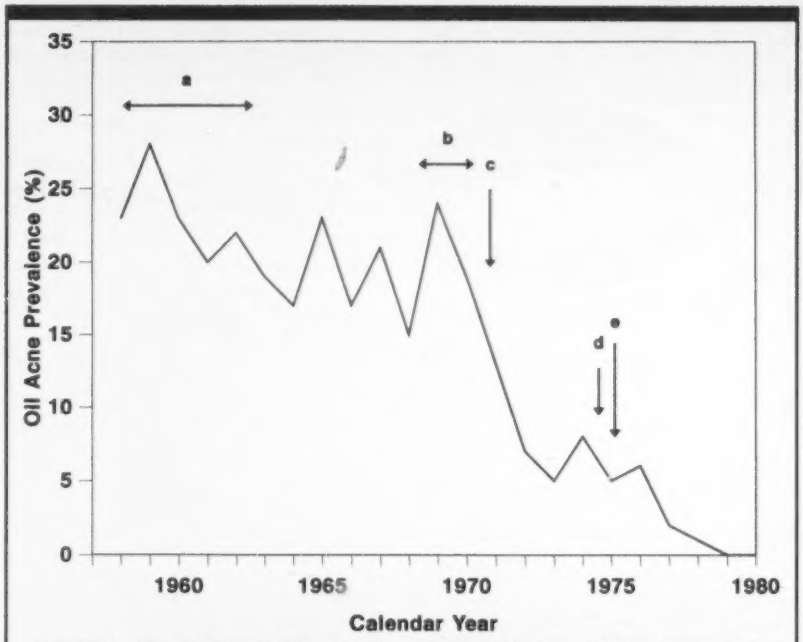

FIGURE 7—Prevalence of oil acne on the forearms of men working in the turning department. Letters refer to major work environment changes: (a) automation of parts removal from machines; (b) further automation allows longer periods away from machines; (c) free underwear provided; (d) free trousers and cotton T-shirts; (e) introduction of solvent-refined instead of acid-refined mineral oils. Conclusion

I have tried to focus this commentary on the full range of opportunities for occupational epidemiology to contribute to prevention. I hope that this paper provokes some further consideration of these opportunities. In closing, however, I feel it is important to reemphasize my concern with the potentially widening gap between epidemiology and public health action. The value of epidemiology to the practice of public health, and in particular the practice of occupational health, is critical. Unfortunately, the academic discipline of epidemiology appears to have become increasingly divorced from applications to prevention in the workplace. The price to be paid is not only financial; the price is also the acceptance of preventable damage to health and loss of life. It is essential that the science of epidemiology and the science of public health be rejoined so that maximum advantage is taken of every opportunity to prevent disease and promote health. □

Acknowledgments

An earlier version of this paper was presented as an invited lecture at the Seventh International Symposium on Occupational Epidemiology held in Tokyo, Japan, in September 1989.

The author would like to express his deep appreciation for the many critical comments and helpful suggestions offered by Ellen A. Eisen, Lawrence J. Fine, Christer Hogstedt, and Linda Rosenstock in the development of the original address and in the final preparation of this document.

Chlorination, Chlorination By-products, and Cancer: A Meta-analysis

ABSTRACT

Objectives. Individual epidemiological investigations into the association between chlorination by-products in drinking water and cancer have been suggestive but inconclusive. Enough studies exist to provide the basis for a meaningful meta-analysis.

Methods. An extensive literature search was performed to identify pertinent case-control studies and cohort studies. Consumption of chlorinated water, surface water, or water with high levels of chloroform was used as a surrogate for exposure to chlorination by-products. Relative risk estimates were abstracted from the individual studies and pooled.

Results. A simple meta-analysis of all cancer sites yielded a relative risk estimate for exposure to chlorination by-products of 1.15 (95% CI: 1.09, 1.20). Pooled relative risk estimates for organ-specific neoplasms were 1.21 (95% CI: 1.09, 1.34) for bladder cancer and 1.38 (95% CI: 1.01, 1.87) for rectal cancer. When studies that adjusted for potential confounders were pooled separately, estimates of relative risks did not change substantially.

Conclusions. The results of this meta-analysis suggest a positive association between consumption of chlorination by-products in drinking water and bladder and rectal cancer in humans. (*Am J Public Health.* 1992;82:955–963)

Introduction

After its first use in the Chicago stockyards in 1908, chlorination of drinking water spread rapidly throughout the United States and produced dramatic reductions in morbidity and mortality associated with waterborne disease.[1] Since then, chlorine has remained the method of choice for water purification; it is currently added to approximately 75% of the nation's drinking water.[2] In 1974, Rook[3] discovered that the combination of chlorine with organic compounds in drinking water produced halogenated organic compounds—chloroform, in particular. In 1975, the National Organics Reconnaissance Survey[4] verified that chlorination by-products were a major contaminant of chlorinated surface water. The study also showed that chloroform concentration correlates highly with the concentrations of other halogenated hydrocarbons and is, therefore, a useful indicator for the presence of these compounds. Since this finding, a plethora of epidemiological studies[5–27] have investigated possible associations between consumption of chlorinated water and cancer. These studies consider a wide range of populations and regions and demonstrate somewhat inconsistent patterns of association. We used meta-analytic methods to pool the results of these studies in an attempt to further our understanding of the relationship between water chlorination and neoplastic diseases. Meta-analysis provides greater statistical power and greater resolution in the estimation of relative risks than do individual studies.

Methods

Identification of Relevant Studies

To identify references pertaining to the relationship between chlorination of drinking water and neoplastic diseases, we used the Medline data retrieval system to search the medical, public health, and biological literature from 1966 through 1991. Relevant papers were obtained and reviewed to locate additional references. Because initial analyses suggested an association between chlorination and both bladder and rectal cancer, the Medline system was used to conduct a second search of the literature over the same 25-year period for papers that considered these neoplasms and mentioned water in the title, abstract, or keywords.

Only those studies that identified morbidity or mortality as well as exposure and potential confounders at the level of the individual (i.e., case-control or cohort studies) were included in the meta-analysis. Studies that considered incidence and exposure at the level of a region or community (i.e., ecological studies) were excluded.

Quality Scoring and Exposure Assessment

Each article was blinded as to authors, institutions, journal, and study re-

sults. Two independent readers scored each paper for quality, using a scoring system that incorporates elements of systems developed by Chalmers et al.[28] and Longnecker et al.[29] Studies were scored on the basis of selection of subjects, measurement of and adjustment for confounding variables, exposure assessment, and statistical analysis. The overall quality score was calculated from three subscores: a general methods score, a data analysis score, and an exposure assessment score. Each subscore was calculated as the percentage of applicable quality criteria that were met in each study. The criteria employed are listed with the results. The cumulative quality score was a weighted average of the three scores, with both general methods and exposure assessment receiving twice the weight of the data analysis score.

Exposure assessment is the most difficult task in a study of this kind. Three factors determine a person's cumulative exposure to an environmental contaminant or risk factor: (1) the environment to which the person was exposed, (2) the level of the proposed agent present in the environment, and (3) the degree to which the person is exposed to that environment. In the current context, these exposures refer to (1) the source of tap water, (2) concentrations of chlorination by-products in that tap water, and (3) the amount of tap water consumed. Although exposure at a fixed point in time (e.g., the time of diagnosis or death) often correlates highly with lifetime exposure, a complete assessment of exposure must also include the historical records for each of these three factors. Thus there are six factors that must be evaluated in each study: three exposure factors plus historical records for each of these factors. The quality of exposure assessment was scored for each study as the percentage of these factors that were evaluated in the study.

Most of the identified studies used consumption of surface water as an indirect measure of exposure to chlorination by-products. Unchlorinated natural waters do not contain significant amounts of chlorinated hydrocarbons. Consequently, the comparison of consumers of chlorinated water with consumers of unchlorinated water provided an acceptable surrogate for comparing exposure vs nonexposure to chlorination by-products.

Similarly, chlorinated surface water contains more chlorination by-products than does groundwater. Whereas virtually all surface water is chlorinated, groundwater tends to be less heavily chlorinated, and in the case of private wells the water is often unchlorinated. In addition, groundwater contains less organic matter than does surface water. Organic matter combines with chlorine to form chlorination by-products. Measurements of chlorination by-products in the drinking water supply[3] have shown that chlorinated surface water contains much higher levels of these by-products than does chlorinated groundwater (medians of 50.7 and 0.8 ppb, respectively) even when the surface water is drawn from protected reservoirs. For these reasons, consumption of surface water vs groundwater was also used as a surrogate for exposure to chlorination by-products.

Although most of the studies used either consumers of groundwater or consumers of unchlorinated water for the control group, one study[22] used consumers of chloraminated water as the control group. Chloramination is a process whereby both chlorine and ammonia are added to filtered drinking water to form chloramines. This chloramine residual is intended to provide sufficient bactericidal capacity to maintain water purity in the distribution system without introducing large amounts of free chlorine. This is a process that minimizes the formation of chlorination by-products. Therefore, this comparison of chlorinated with chloraminated water consumption provided a surrogate for exposure vs nonexposure to chlorination by-products.

Chloroform is the most common chlorination by-product and consequently has been the focus of health concerns related to water chlorination. Several studies included measured chloroform levels in their exposure assessments. Although recent research[30] suggests that other by-products may be more toxic, chloroform concentration correlates well with the concentration of other by-products.[4] Therefore, measures of chloroform concentrations were deemed to be the most accurate measures of chlorination by-products.

Extraction of Relative Risk Estimates

The odds ratios or relative risks for cancer among consumers of drinking water containing chlorination by-products were identified for each of the selected studies. Exposure was defined on the basis of the categorization of subjects as consumers of chlorinated water or surface water in the individual studies; nonexposure was defined on the basis of the categorization of subjects as consumers of nonchlorinated water, chloraminated water, or groundwater. When risks were stratified by sex, they were recorded as such. The variance of the natural log of the odds ratio or relative risk was derived with the statistics provided in the particular study. If an odds ratio was reported to be different from unity with P less than a specified significance level, the variance was calculated assuming P equal to this maximum value (e.g., given $P < .05$, $P = .05$ was assumed). Calculation of a variance on the basis of this conservative assumption resulted in the maximum possible variance and minimized the probability of a type I error in the meta-analyses. If a study reported a coefficient from a logistic regression, the regression coefficient was used along with an estimate of average exposure for the exposed sample to calculate an estimate for the relative risk. Studies that stratified according to level of exposure were analyzed by pooling the values from each stratum to yield a single value from each study estimating the relative risk for the exposed vs nonexposed populations.

The neoplasms considered in these studies were sufficiently rare that odds ratios were deemed to be close approximations of relative risks. Therefore, we did not distinguish between odds ratios and relative risks in our meta-analysis. All results listed may be considered as relative risk estimates.

Some studies reported morbidity data and others reported mortality data. For relative risks for mortality to differ from relative risks for morbidity, the exposure in question must alter disease survival. We have no reason to expect that water chlorination alters disease survival. To evaluate this possible bias, we analyzed the two groups separately as part of the sensitivity analysis described below.

Meta-analysis

The relative risk estimates were analyzed in two stages, a meta-analysis of all studies and a meta-analysis of selected subgroups of studies. In the first stage, meta-analyses were performed for each cancer site by pooling all pertinent studies without stratifying for sex. If a given tumor site was evaluated in at least two studies, relative risk estimates were pooled and analyzed for that site. The random effects model described by DerSimonian and Laird[31] was used to combine the collected values. This procedure yielded a single estimate of the relative risk for or-

gan-specific neoplasms in individuals exposed to chlorination by-products in drinking water.

Meta-analysis, in addition to improving our ability to identify small but significant relative risks in the context of apparently contradictory research findings, enhances our capacity to interpret truly negative results. Statistical power is a measure of the probability of finding a significant difference, assuming a specified effect and a specified type I error rate. A detailed analysis of statistical power was carried out for each cancer site. For each negative result ($P > .05$) the probability of detection of relative risks of 1.2, 1.4, and 1.6 was determined on the basis of the calculated relative risk estimate and variance.

Sensitivity and Dose-Response Analyses

If the first analysis demonstrated a significant association ($P < .05$) between chloroform exposure and neoplastic disease for a given site, a second set of more detailed analyses was performed on relative risk estimates pertaining to that site. The influence of potential confounding variables, sex differences, quality score, and accuracy of exposure assessment on the effect of chlorination by-products were all evaluated in this stage. In addition, studies that provided dose-response relationships were pooled separately.

The effect of inaccurate determination of exposure to chlorination by-products (misclassification bias) and the effect of incomplete control for confounding variables were of particular concern. The authors of each study chose to adjust for a slightly different set of potential confounding variables. A failure to adjust for some factor (e.g., smoking in bladder cancer) might well lead to erroneous estimates of risk. To determine whether such differences among studies might have an impact on the pooled results, individual studies that controlled for confounders were grouped for separate meta-analyses. The relative risk estimates of cancer for each site were also pooled separately for each sex. Studies were also divided into two groups and analyzed according to their score for overall quality and for quality of exposure assessment. In each case, studies with scores above the mean were compared with studies whose scores were below the mean.

A conventional literature review pools findings implicitly by weighting according to a subjective and unspecified quality scoring system. Although weighting by quality score is intuitively appealing, there is no established protocol either for calculating a quality score or for weighting according to score. As a simple test, we repeated the meta-analyses for bladder and rectal cancer, using quality scores as weights.

Meta-analysis was also used to evaluate dose-response relationships. For each study that stratified by level of exposure, relative risk estimates for high, medium, and low levels of exposure were determined. The studies were then combined, with each level pooled separately.

The dose-response analysis excluded those studies that evaluated exposure as a dichotomous variable. In order to determine the impact of this exclusion, we repeated the dose-response analysis with these studies included. In order to include these studies, we assumed that the exposed group in studies with dichotomous exposure measures had experienced moderate levels of exposure.

Results

Literature Search

The literature search identified 10 case-control studies[15–24] and two cohort studies[25,26] that investigated the relationship between some measure of exposure to chlorination by-products in the drinking water and cancer. One case-control study[19] considered source of drinking water as one of many potential risk factors for bladder cancer. The association between bladder cancer and drinking water was stated to be nonsignificant, but numerical results were not reported, making the inclusion of this study in the meta-analysis impossible. One cohort study considered bladder cancer in a group of workers with exposure to a known carcinogen. This cohort was deemed not to represent the general population and was also excluded. The 10 studies that were entered into the meta-analysis are listed in Table 1.

One study[22] evaluated a variety of neoplasms and found an association between bladder cancer and chlorination. It was followed by a second study[27] that analyzed the same sample with more thorough methods for assessment of exposure to chlorination by-products. The second study reported two odds ratios, one comparing high exposure to no exposure and the other comparing moderately high to moderately low exposure. The second of these two odds ratios was used in the analyses of bladder cancer except in the dose-response analysis, in which both values were used.

Quality Scoring

Table 2 shows the results of the quality scoring procedure. All 10 studies identified the source of drinking water at the residences of the subjects either at the time of the study or at the time of death. Chloroform concentrations and specific tap water consumption rates for the subjects were determined in a minority of the studies (4 in both cases). Historical patterns of drinking water consumption were not quantified in any of the studies. Historical sources of tap water were evaluated in 6 of the studies. No study used historical values of chlorination by-product concentrations, because these are not generally available, but 7 used some portion of the historical record, such as water utility chlorination logs, to estimate historical levels of chlorination by-products in drinking water. The studies are listed in Table 1 in order of their quality scores.

Selection of cases and controls followed accepted procedures and was not a major source of bias in these studies. Information bias associated with failure to adjust for confounding variables may have been more of a problem. With the exception of age (100%), sex (100%), population density (80%), and race (60%), potentially confounding variables were not generally adjusted for. Statistical analyses in these studies were usually thorough with regard to the determination of relative risks, but they tended to be less rigorous with regard to analyzing other aspects of the sample groups. Although most studies listed P values (70%), adjusted for confounders (90%), and identified specific tests used (80%), few listed or analyzed demographic data (40%). Only one study (10%) provided power calculations.

Extraction of Risk Estimates and Meta-analysis

Table 3 lists the relative risk estimates extracted from each study. Although 39 of these 64 estimates (64%) are greater than 1.00, only 19 (30%) are significantly greater than 1.00 ($P < .05$).

Table 4 lists the results of the organ-specific meta-analyses, with power calculations. Bladder cancer has an overall relative risk estimate of 1.21 (95% CI: 1.09, 1.34). Rectal cancer has a relative risk estimate of 1.38 (95% CI: 1.01, 1.87). Lung, breast, brain, kidney, liver, pancreatic, esophageal, colonic, and gastric neoplasms all have pooled estimates of relative risk that are not significantly different from unity.

Note that all 12 relative risk estimates were greater than 1.00, suggesting that the

TABLE 1—Summary of Studies Included in the Meta-analysis Relating Chlorination By-products in Drinking Water to Cancer

Authors	Year[a]	Population	Cases	Controls	Exposure Assessment	Covariates	Analysis
Cantor et al.[20]	1987 (78)	White residents of 10 US regions	2982 newly diagnosed cases of bladder cancer	Community controls matched 2:1 for age, sex, and region by random dialing and Medicare files	History of residence, and beverage consumption combined with survey and sampling of water utilities	Age, sex, cigarette consumption, occupation, population of place of longest residence	Logistic regression
Young, Wolf, Kanarek[24]	1987 (75)	Wisconsin residents	347 newly diagnosed cases of colon cancer	General population controls matched 2:1 for age and sex	Water consumption by interview and chloroform by historical records and measurement	Age, sex, population of place of residence	Logistic regression
Zierler, Danley, Feingold[22,27b]	1986, 1988 (22, 71)	Massachusetts residents	51 645 kidney, bladder, stomach, pancreas, colon, lung, breast cancer deaths	Deaths from cardiovascular, cerebrovascular, or pulmonary disease or lymphatic cancer by death certificate	Chlorination/ chloramination at address on death certificate	Age, sex, surface/ groundwater, population density, and level of poverty in county of residence	Odds ratios with Mantel-Haenszel adjustment
Cragle, Shy, Struba, Siff[21]	1985 (65)	Patients of 7 North Carolina hospitals	200 newly diagnosed cases of colon cancer	Noncancer hospital controls matched 2:1 for age, sex, vital status, and hospital	Years of exposure to chlorinated water by residential history and survey of water utilities	Age, sex, genetic risk, dietary fiber, region, urban residency, smoking, alcohol use, education, number of pregnancies	Logistic regression
Lawrence, Taylor, Trock, Reilly[23]	1984 (62)	New York female teachers	395 colorectal cancer deaths	Noncancer deaths matched 1:1 for age and sex by death certificate	20-year employment and residential history with model for chloroform levels	Age, marital status, population density, type of surface water	Logistic regression
Wilkins, Comstock[25c]	1981 (61)	31 000 residents of Washington County, MD	Diagnosis of cancer in 12 years following initial survey	*Unexposed:* Deep well users	*Exposed:* Users of chlorinated surface water in Hagerstown, Md	Age, sex, smoking, marital status, education	Logistic regression
Gottlieb, Carr, Clarkson[18]	1982 (49)	Louisiana residents	10 205 kidney, bladder, stomach, liver, and colorectal cancer deaths	Two groups of cancer deaths and one of noncancer deaths matched 1:1 for age, sex, race, and parish by death certificate	Chlorinated/ unchlorinated water at address on death certificate and at birthplace	Groundwater/surface water, cardiovascular disease	Stratified odds ratio with χ^2 test
Brenniman, Lagos, Amsel, Namekata, Wolf[19]	1980 (46)	White residents of Illinois	3208 gastro-intestinal and urinary tract cancer deaths	Noncancer deaths matched 14:1 for age, sex, and county by death certificate	Chlorinated/ unchlorinated water at address on death certificate	Urbanicity, population density	Odds ratios with Mantel Haenszel adjustment
Young, Kanarek, Taisle[17]	1961 (45)	White female residents of Wisconsin	8029 cancer deaths	Noncancer deaths matched 1:1 for age, sex, race, and county by death certificate	Chlorinated/ unchlorinated water at address on death certificate	Population density, occupational risk, marital status, rural runoff in water	Logistic regression
Alvanja, Goldstein, Susser[15]	1978 (43)	NY State residents	3446 gastro-intestinal and urinary tract cancer deaths	Noncancer and lung cancer deaths matched 1:1 for age, sex and county by death certificate	Chlorinated/ unchlorinated water at address on death certificate	Urbanicity, occupation	Stratified odds ratio with χ^2 test

Note. Studies are listed in descending order with respect to the quality score. (Scores are presented in parentheses after the year.)
[a]Overall quality scores that are listed with the year may range from 0 to 100.
[b]The second Zierler study[27] was conducted on the same population, but was limited to bladder cancer. Note that this study had a substantially higher quality score than the earlier study (71 vs 22).
[c]Wilkins and Comstock's study was a cohort study. All other studies listed were case-control studies.

association of chlorination by-products with cancer, although modest, is more general than the two statistically significant sites. Pooling all 12 sites yields an estimate of the overall relative risk for cancer associated with chlorination by-products in drinking water of 1.15 ($P < .0001$). Eliminating bladder, rectal, and colorectal cancer and repeating this overall meta-analysis results in a relative risk estimate of 1.09 ($P = .006$).

The power of the negative meta-analyses to detect a relative risk of 1.2 at a significance level of .05 ranges from .27 for breast cancer to .70 for pancreatic cancer, compared with a power of only .06 for brain tumors. For a relative risk greater than 1.6, power for all of the sites with negative findings rises above .90, with the exception of that for brain cancer, which only reaches .18.

Sensitivity and Dose-Response Analyses

Of the sites listed, only bladder and rectal cancer met the established criteria for further analysis. In addition, colonic neoplasms were included in these analyses to evaluate the apparent differences between risks for colonic and rectal neoplasms given the anatomic and physiologic relationship between the two sites. For bladder cancer, the effects of adjusting for smoking, occupation, or population density were evaluated. For rectal and colon cancer, only population density was analyzed (other risk factors, such as diet, were not included in the studies selected). Table 5 lists the results of these analyses.

For bladder cancer, adjustments for confounders do not appear to alter the association with exposure to chlorination by-products. Separate meta-analyses of studies that adjusted for population density, smoking, or occupation yielded relative risk estimates of 1.20, 1.25, and 1.22, respectively. The single study that adjusted for all three factors had a relative risk estimate of 1.19. Estimates of relative risk for bladder cancer were 1.17 for females and 1.24 for males.

The bladder cancer studies with quality scores above the average for this group had a pooled relative risk estimate of 1.25 (95% CI: 1.08, 1.45). Those with below-average quality scores had a pooled value of 1.16 (95% CI: 0.96, 1.40). Improved exposure assessment increases the estimate of relative risk and narrows the confidence limits around this estimate from 1.16 (95% CI: 0.96, 1.40) to 1.25 (95% CI 1.09, 1.45).

TABLE 2—Items Used in Quality Scoring for Case-Control and Cohort Studies of the Association between Consumption of Chlorination By-products in Drinking Water and Cancer

Quality Scoring Item	Studies Complying, %[a]
Case and control selection	
Random selection of cases	90
Selection blinded to exposure status	70
Specific disease criteria given	100
Disease validated by histology or other "gold standard"	40
No known association between control status and exposure	70
Random selection of controls	80
Adjustment or matching for confounders	
Age	100
Sex	100
Population density	90
Race	60
Smoking	40
Occupation	40
Diet	10
Exposure assessment	
Drinking water source for study subjects identified	100
Tap water consumption for study subjects assessed	40
Chloroform in drinking water sources measured	40
Historical drinking water sources for subjects evaluated	80
Historical patterns in tap water consumption for subjects evaluated	0
Historical chlorination levels in water sources evaluated	70
Data analysis	
Power calculation performed	10
Demographic data listed	40
Statistical analysis of demographic data	10
Correlations between independent variables listed	20
Precise *P* values listed	70
Test specified	80

[a]If compliance is not specifically indicated in the text, noncompliance is assumed.

For rectal cancer, adjustments for confounders do not appear to alter the association with exposure to chlorination by-products. Separate meta-analysis of studies that adjusted for population density yielded a relative risk estimate of 1.33. Estimates of relative risk for rectal cancer were 1.11 for females and 1.24 for males.

The rectal cancer studies with quality scores above the average for this group had a pooled relative risk estimate of 1.91 (95% CI: 1.56, 2.35). Those with below-average quality scores had a pooled value of 1.07 (95% CI: 0.89, 1.29). Improved exposure assessment increases the estimate of relative risk from 1.23 (95% CI: 0.89, 1.70) to 1.57 (95% CI: 1.09, 2.24).

A different picture emerges with regard to colon cancer. No grouping of studies, either by sex or by adjustment for population density, results in a significant estimate of relative risk for colon cancer. In the quality score breakdown, high-quality-score studies had lower risk estimates than did low-quality-score studies (1.10 [95% CI: 0.79, 1.53] vs 1.13 [95% CI: 0.86, 1.48]).

Weighting by quality score alone produced relative risks of 1.34 for bladder cancer and 1.46 for rectal cancer (95% CIs: [1.20, 1.49] and [1.29, 1.64], respectively).

Estimates of relative risk for bladder, colon, and rectal cancer at low, medium, and high exposure levels are shown in Table 6. The values for bladder cancer rise steadily from 1.03 to 1.20 to 1.41 and demonstrate increasing levels of significance with increasing exposure level. Rectal cancer also shows a pattern of increasing relative risk with increasing cumulative exposure from 1.13 to 1.29 to 2.04. The inclusion of studies with dichotomous measures of exposure produces estimates of relative risk for moderate exposure that fall, in each case, between the estimates for high and low exposure.

A comparison between studies evaluating incidence and those evaluating mortality did not show a substantial difference between the two categories. For bladder cancer, the pooled relative risk estimates were 1.22 (95% CI: 1.03, 1.44) for the five mortality studies and 1.24 (95% CI: 0.92, 1.67) for the two incidence stud-

Pancreas	6	1.05	0.91, 1.22	.48	.70	>.99	>.99
Rectum	6	1.38	1.01, 1.87	.04	...	...	...
Stomach	6	1.14	0.94, 1.38	.19	.46	.93	>.99

[a]Number of studies evaluating specific cancer site.
[b]Power is defined as $1 - \beta$, where β is the probability of type II error at the given levels of true relative risk and significance. Statistical power was not calculated if the meta-analysis was significant.

ies. For rectal cancer, these estimates were 1.37 (95% CI: 0.98, 1.92) for the five mortality studies and 1.42 (95% CI: 0.70, 2.88) for the lone incidence study. This stratified analysis suggests that incidence studies in our analysis do not yield different relative risk estimates from mortality studies.

Discussion

The data support a significant association between bladder cancer and exposure to chlorination by-products in drinking water. This association appears to follow a dose-response relationship. Controlling for potential confounders (i.e., sex, smoking, urban living, and occupational risk) does not diminish this association. The association of rectal cancer with chlorination by-products follows a pattern similar to that of bladder cancer.

The association of chlorination by-products with bladder and colon cancer increases with improved exposure assessment and higher overall study quality. This pattern strengthens the evidence for an association between both rectal and bladder cancer and chlorination by-products and suggests that the true relative risks may be higher than those listed here.

Chlorination by-products are associated with cancer of the rectum, but not cancer of the colon. The bladder and the rectum both serve a similar physiological function by storing concentrated excretory products. One might speculate that the epithelial tissue at both sites is exposed to higher levels of chlorination by-prod-

		Low	1.11	0.87, 1.41

[a]This group includes only those studies that considered both sexes. Hence the results are different from the values for all relevant studies.

TABLE 6—Meta-analytic Estimates of the Association between Bladder and Colon Cancer at Specified Levels of Cumulative Exposure to Chlorination By-products

Site	Level of Exposure	Relative Risk Estimate	95% CI
Bladder	Low	1.03	0.85, 1.24
	Moderate[a]	1.20	1.05, 1.37
	Moderate[b]	1.20	1.04, 1.38
	High	1.41	1.24, 1.62
Rectum	Low	1.13	0.61, 2.09
	Moderate[a]	1.29	1.00, 1.67
	Moderate[b]	1.49	1.10, 2.01
	High	2.04	1.18, 3.53

[a]This category includes only data from those studies that ranked a middle level of exposure.
[b]This category includes all studies for which exposure was dichotomous, in addition to studies ranked a middle level of exposure.

ucts and is therefore at increased risk for the development of neoplasia.

The most important potential confounder not adjusted for in these studies is diet. If consumption of a diet high in fat and low in fiber were associated with consumption of chlorinated water, one could argue that the observed association is simply a surrogate for dietary risk. We know of no such association. In addition, if diet were responsible for the observed association with rectal cancer, we would expect to see the same association with colon cancer. The marked differences in these associations tend to refute the contention that diet is an explanatory factor for observed associations.

With regard to other sites for neoplastic disease, relative risks ≤ 1.2 cannot be excluded with a high degree of confidence for any of the sites considered. A relative risk ≥ 1.6 for cancer associated with chlorination by-products can, however, be excluded with a high degree of confidence, on the basis of current evidence, for most sites. The meta-analysis for brain cancer lacks the power to exclude with any certainty even a high relative risk for cancer.

The present study has identified a clear and significant association between neoplastic disease and the consumption of water containing chlorination by-products. Precise cause and effect cannot be determined. The possibility that chlorination may serve as a marker for some other aspect of drinking water quality or an associated geographic or demographic variable cannot be entirely discounted, given the available research. If chlorination by-products are carcinogens, the identity of the compound or compounds involved is unclear. One agent actively being investigated in this context is a chlorinated hydroxy-furanone recently identified as an extremely potent mutagen present in chlorinated surface water.[30]

If we posit that the association demonstrated between chlorination by-products and cancer represents a causal relationship in some way, the positive relative risks identified for bladder and colon cancer can best be interpreted in the context of attributable proportions (i.e., that portion of cases that can be attributed to a given risk factor[32]). By a conservative estimate, based on the 54% of the population that consumes chlorinated surface water (rather than the 75% that consumes chlorinated water), a 21% increase in the risk for bladder cancer and a 38% increase in the risk for rectal cancer translate into attributable proportions of 9% and 15%, respectively. With US incidence rates for bladder and rectal neoplasms of 47 000 and 44 000 cases per year, respectively,[33] these proportions suggest that about 4200 cases (9%) of bladder cancer per year and 6500 cases (18%) of rectal cancer per year are associated with the consumption of chlorinated water. The higher estimates for relative risk associated with more accurate assessment of exposure suggest that the true attributable proportions may be higher than those stated here.

Of the original papers included in the meta-analysis, only three of the seven bladder cancer studies and two of the six rectal cancer studies were statistically significant. Consequently, a standard review of the literature might conclude, erroneously, that no significant risk exists. Seemingly small risks posed by environmental factors may have major health impacts because of the large numbers of people exposed. The results of the meta-analysis demonstrate the utility of this methodology in the identification of important but elusive relative health risks and suggest that a wider application of meta-analysis is warranted.

Our findings are in no way intended to suggest that the disinfection of drinking water should be abandoned. The potential health risks of microbial contamination of drinking water greatly exceed the risks described above. Nonetheless, these findings should provide an impetus to identify, develop, and implement disinfection strategies that are not associated with adverse health effects. □

Call for Abstracts for Injury Control/Emergency Services Late-Breaker Session

The Injury Control and Emergency Health Services Section will again sponsor a "late-breaker" session during the APHA 1992 annual meeting in Washington, DC. The session will be held on Tuesday, November 10, and will feature work completed within the last few months (after the deadline for consideration in the regular symposia of the APHA annual meeting).

Submit abstracts of 250 words or fewer (any format) and a return envelope to Richard Wanweiler, Division of Injury Control, Centers for Disease Control, Mail Stop F-36, Atlanta, GA 30333; tel. (404) 488-4680.

Abstracts must be received by September 1, 1992. Decisions will be made by September 15, 1992.

Epidemiological Data on US Coal Miners' Pneumoconiosis, 1960 to 1988

Michael D. Attfield, PhD, and Robert M. Castellan, MD, MPH

ABSTRACT

Objectives. Statistics on prevalence of pneumoconiosis among working underground coal miners based on epidemiologic data collected between 1960 and 1988 are presented. The main intent was to examine the time-related trend in prevalence, particularly after 1969, when substantially lower dust levels were mandated by federal act.

Methods. Data from studies undertaken between 1960 and 1968 were collected and compared. Information for the period 1969 to 1988 was extracted from a large ongoing national epidemiologic study. Tenure-specific prevalence rates and summary statistics derived from the latter data for four consecutive time intervals within the 19-year period were calculated and compared.

Results. The results indicate a reduction in pneumoconiosis over time. The trend is similar to that seen in a large radiologic surveillance program of underground miners operated concurrently.

Conclusions. Although such factors as x-ray reader variation, changes in x-ray standards, and worker self-selection for examination may have influenced the findings to some extent, adjusted summary rates reveal a reduction in prevalence concurrent with reductions in coal mine dust levels mandated by federal act in 1969. (*Am J Public Health.* 1992; 82:964–970)

Introduction

The National Institute for Occupational Safety and Health (NIOSH) receives frequent requests for information on the prevalence of coal workers' pneumoconiosis (CWP), but no current and comprehensive statistics are available in a convenient format. Two reports have been compiled to fill this gap. The first, this paper, concerns the findings from epidemiological studies undertaken from 1960 to 1988, including the National Study of Coal Workers' Pneumoconiosis (NSCWP), a large nationwide epidemiological study managed by NIOSH. The second[1] deals with information from the Coal Workers' X-ray Surveillance Program (CWXSP) from 1970 to 1986.

Among the provisions of the 1969 Federal Coal Mine Health and Safety Act[2] was a directive that a research program be set up to inquire into the respiratory health of US coal miners. The NSCWP, begun in 1969 and still in progress, was the response to this mandate. Based on mines selected from all the major coalfields, it is the largest and longest-running epidemiological study of coal miners in the United States. Many of the mines were included in some earlier medical[3] and environmental[4] investigations. Medical examinations were undertaken at these NSCWP mines up to four times between 1970 and 1988.

The NSCWP was designed to estimate levels of lung disease in underground coal miners, and to study the relationship between disease and the level and constituents of dust exposure. Results from the study have shed a great deal of light on CWP in US coal miners,[5–10] as well as on other lung diseases.[11–13] To date, however, the CWP reports based on NSCWP data have been tailored to suit a variety of specific inquiries, and their resulting lack of uniformity in format makes comparison among them difficult. Furthermore, careful review of these reports reveals apparent inconsistencies between the prevalences of CWP published at different times—notably, between those published at the start of the study and those disseminated later. The objective of the present paper is to present all the NSCWP-generated CWP prevalence estimates, along with those of preceding US studies, in a unified manner, and to review and explain the differences and inconsistencies.

Coal Workers' Pneumoconiosis. CWP is almost always identified in living coal miners by examination of the chest radiograph. Coal mine dust deposits in the lung give rise to radiographic opacities. Small (less than 1 cm diameter) opacities are classified into four major categories (0, 1, 2, and 3) by reference to standard films representing levels of profusion. The current reference is the 1980 International Labour Office (ILO) classification system.[14] Small opacities are also classified according to shape (rounded or irregular). The actual approach to differentiating between small rounded and small irregular opacities and to determining profusion has differed over the years (see below). This report concentrates on small rounded opacities because that type has been conventionally associated with coal mine dust exposure.[15]

Simple CWP is manifested by small opacities on the chest radiograph. It is dis-

This paper was submitted to the Journal July 1, 1991, and accepted with revisions March 23, 1992.

tinguished from complicated CWP, also known as progressive massive fibrosis (PMF), a more advanced form of CWP manifested by large radiographic opacities (at least 1 cm in diameter) on the chest radiograph.

Historical Information. Prior to the 1969 promulgation of federal limits on airborne respirable dust concentration in US underground coal mines, respirable dust levels substantially exceeded the current federal limit of 2 mg/m^3. For example, Jacobson[4] showed that average dust concentrations for certain miners working at the coal face were close to 6 mg/m^3, and that the mean concentrations for most other underground jobs were above 2 mg/m^3.

Shown in Table 1 are summary results on prevalence of category 1 or greater CWP derived from eight reports published between 1961 and 1970.[3,16-22] Eleven regions were involved, ranging from the anthracite coalfield of Pennsylvania to southern mines located in Alabama and to western mines in Utah. This review extends that of Morgan.[23] With the exceptions noted in the footnotes to the table, all the information concerns working coal miners and is based on the 1959 ILO classification.[24] For these tabulations, category Z opacities (suspicious markings) were classified with those in category 0.

Table 1 arranges the studies according to rank of coal (higher coal rank implies an older coal of higher percentage carbon), there being evidence that CWP incidence varies with coal rank.[5] The regions considered were high rank (anthracite), medium-high rank (low volatile bituminous), medium rank (mainly high volatile "A" bituminous), and medium-low rank (mainly high volatile types "B" and "C" bituminous). The results confirm the previously reported association between CWP prevalence and coal rank. Mean mining tenure and age were similar across coal rank groups and therefore were unlikely to have been responsible for the observed coal rank trend. A fair amount of interstudy variation within coal rank groups is seen, which may have resulted from the use of different x-ray standards and readers. Varying rates of worker participation and differences in dust exposure (data not available) may also have contributed to the variation.

Tenure-specific prevalences from these studies, where available, are plotted in Figure 1. In every study, prevalence of small rounded opacities increased with increasing tenure. Agreement is quite good for those studies from the lower rank regions.

Information on more advanced profusions of small opacities was available from only four studies, and findings for category 2 or greater small opacities varied from 22% in working miners in the high rank region,[16] to 21% and 33% in medium-high rank coal miners,[18,19] to 7% in medium rank miners.[22] Large opacity prevalence also varied fairly consistently with

TABLE 1—Prevalence Rates of Coal Workers' Pneumoconiosis (Category 1 or Greater) for Some US Studies Undertaken between 1961 and 1970, In Order of Coal Rank

Study (by Probable Coal Rank)	Prevalence of CWP (Category 1 or Greater)	PMF	Mean Age, y	Mean Tenure, y		Comments (See Below)

J. Illinois/Indiana[3]	6	1.5	48	...	20	5
K. Utah[3]	4	0.7	51	...	20	5

Notes. PMF = progressive massive fibrosis; Mine = all work in coal mining; UG = work underground.
1. The 1959 ILO classification[24] was used.
2. Exact figure for average age is not given; figure given here has been estimated from age distribution data.
3. Group contains both current and ex-miners, and could not be subdivided.
4. Radiographic classification is not stated but is probably the ILO 1959 scheme,[24] given that the study was undertaken from 1963 to 1964.
5. The classification used is not stated explicitly. The reading sheet shown in the report looks very similar to that of the ILO 1968 classification,[25] but Morgan[23] states that the ILO 1959 classification system was used.

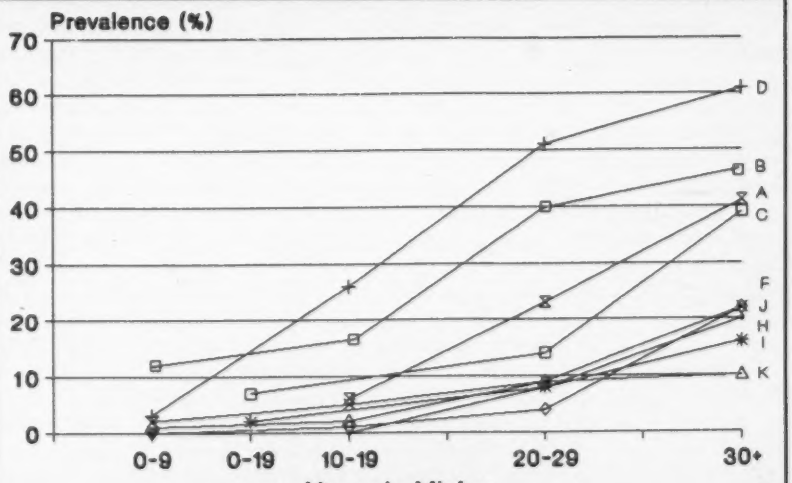

FIGURE 1—Prevalence of category 1 or greater small rounded opacities by tenure in mining for studies of underground US coal miners published between 1961 and 1970. (See Table 1 for the studies corresponding to the letters.)

coal rank, from about 10% in the high rank region[16] to about 1% in the medium-low rank region[3] (Table 1). Prevalences of large opacities were markedly higher in workers who were close to retirement age, with 19%, 18%, and 9% prevalences being reported for high, medium-high, and medium rank regions of Pennsylvania, respectively.[16,18,22]

NSCWP Methods

Survey Information

The NSCWP has been conducted in rounds of medical surveys. Round 1 examinations were conducted from 1969 to 1971, round 2 from 1972 to 1975, round 3 from 1977 to 1981, and round 4 from 1985 to 1988. The procedure in each of the first three rounds was to examine the miners at the mine site, either before or after their work shift, using a mobile x-ray trailer. Forty mines have been visited at one time or another over the course of the study. Thirty-one mines were visited at round 1. The principal criteria at round 1 for the selection of mines were (1) an expected life of the mine of at least 10 years, (2) a work force of at least 100 miners, (3) a geographic and geologic spread, and (4) accessibility for the field examination trailer. Owing to unexpected mine closings, nine other mines were substituted in round 2 following the same selection criteria.

Rounds 1 to 3 were a series of cross-sectional studies at virtually the same group of mines. Round 4 was organized very differently, being a follow-up of selected miners from the first two rounds. As a consequence, most of the round 4 examinations were not undertaken at the original mine sites but comprised what were termed "community surveys." Based on residence addresses, suitable clusters of miners and ex-miners were identified from the follow-up cohort. The mobile examination trailer was set up at a central location in each of 22 communities where clusters occurred, and individual contacts were made to encourage miners in the follow-up cohort to participate in the examination. In addition, mine surveys were held at three of the original mines; more were not possible because many of the original mines had closed or were nonoperational owing to the coal mining recession that occurred in the mid-1980s.

Low participation rates have been a problem with some rounds of the NSCWP. Although participation was very good at round 1 (accounting for 90% of those eligible at time of examination), the next two surveys were marked by a substantial decline in participation to 75% at round 2 and to 52% at round 3. The change in study design and survey strategy in round 4 led to an improvement in participation, accounting for 70% of those selected at the community studies and better rates at the mine site surveys.

X-ray Readers, X-ray Classifications, and Associated Methods

Apart from a switch to rare earth screens in 1985, the x-ray equipment and methods have changed little over the course of the NSCWP. Throughout the study, three x-ray readings were obtained for each chest radiograph. To date, resources have not been available to reread all the films using the same readers, protocol, and classification. Therefore, the information presented here is based on the original readings made at each round of the NSCWP.

The round 1 films were classified using the Union Internationale Contre le Cancer (UICC)/Cincinnati (U/C) classification system.[26] Of the three interpreters employed, only two specifically classified small rounded opacities (readers 1 and 2). These were both expert readers, who had collaborated with others in developing the UICC/Cincinnati classification system.[26] Later examination of their readings revealed, however, that reader 1 found improbably high levels of abnormality. His results give rise to prevalences that deviate substantially from every other source, including prior studies, other NSCWP surveys, concurrent surveillance program data,[1] and readings from a group of British interpreters.[27] Because of this discrepancy, his results have not been included in this analysis. Instead, the round 1 data presented here are those of the single remaining reader who classified small rounded opacities (reader 2); this interpreter's findings were much more consistent with those of the other sources noted above. (The readings of reader 1 were included in an earlier analysis,[5] which thereby reported a considerably greater prevalence of CWP than that given here.)

The 1971 ILO U/C classification system[28] was adopted for round 2. Readers 2 and 3 from round 1, along with seven other B readers (readers who have taken and passed a NIOSH-administered test of competency in reading for the pneumoconioses),[29] classified radiographs in the second round. All cases included in this analysis were based on median determinations of three readings of small rounded opacities.

The round 3 results presented here were also based on median determinations of small rounded opacities, this time made by three B readers using the 1971 classification. None of the three readers had participated in the earlier rounds.

For round 4, each film was independently read by three B readers using the 1980 ILO classification system.[14] Because the 1980 system does not permit profusions of small rounded and small irregular opacities to be classified separately, small rounded opacity profusion was put equal to the overall profusion score if rounded opacities were reported to predominate. However, if irregular opacities were said to be more common, the small rounded opacity profusion was set to 0. This approach probably tends to exaggerate the rounded profusion category when the primary type is rounded, and to underestimate the rounded profusion category when irregular opacities predominate.

To select readers for round 4, readings of all B readers who had read films for round 4 of the CWXSP were tabulated, and the readers were ranked according to amount of abnormality detected. Three readers lying in the midrange were then selected. None of these readers had participated in earlier rounds of the NSCWP.

In addition to small rounded opacities, this report also presents information on progressive massive fibrosis. The data were derived from reader 2 at round 1 and from medians of three readings at each of the subsequent rounds. Some summary statistics are also given on small combined opacity prevalences obtained similarly from reader 2 at round 1 and from medians elsewhere.

Throughout the NSCWP, occupational histories were obtained from the miners using a standardized questionnaire that varied little over the four rounds.

The tabulations that follow are based on all complete sets of data (readable x-rays and available tenure information) from each round, with the exception of round 4. For round 4, ex-miners who said they had left work because of health reasons were not included in order to make round 4 results more compatible with those from the earlier rounds. In general, these ex-miners had more abnormality than the others. However, laid-off miners and ex-miners who had taken other jobs were included with the current miners in the round 4 tabulations. The great major-

ity of these miners had left mining within a year or two before the medical survey.

NSCWP Results

Distribution of Examined Miners by Geologic Region

Table 2 shows how the data for those cases with valid x-ray readings were distributed across four geologic regions. A slight temporal movement from high to low rank coal areas is apparent. This generally reflects the pattern of mine closings that has occurred over the past two decades, particularly in the high rank region. Note, however, that the percentages of miners in the medium and medium-low rank regions remain almost constant over the four rounds.

TABLE 2—Miner Location by Round and Coal Rank Region as Defined by the National Study of Coal Workers' Pneumoconiosis

Region	Round 1[a] Miners	Round 2[a] Miners	Round 3[a] Miners	Round 4[a] Miners
High rank, %	6	3	0	0
Medium-high rank, %	15	14	19	17
Medium rank, %	55	58	55	51
Medium-low rank,%	25	25	27	32
Number of participants	9078	9347[b]	5275	3534
Number of x-ray readings	9034	8385[b]	5131	3451

[a]Percentages were based on the number of x-ray readings.
[b]Films for miners at two mines at round 2 were read by one reader only, leading to a larger difference between the numbers of participants and readings than exist for the other three rounds.

Distribution of Examined Miners by Tenure

The tenure distribution of coal miners has changed considerably over time owing to economic activity and other factors (Table 3). Prior to 1973, the coal mining work force was quite elderly, as the industry had been undergoing a long-term decline. Over the next few years, many of the older and longer-tenured miners left mining and were replaced by younger workers. More importantly, a large number of new miners were hired in the wake of the energy crisis–related mining expansion that took place in the mid-1970s. Since then, the mean age of the work force has been gradually rising.

TABLE 3—Tenure in Mining by Round as Defined by the National Study of Coal Workers' Pneumoconiosis

Tenure Group	% Round 1 Miners (n = 9034)	% Round 2 Miners (n = 8385)	% Round 3 Miners (n = 5131)	% Round 4 Miners (n = 3451)	% 1986 Survey Miners (n = 78 741)
0	0.0	2.4	1.1	2.4	2.0
1	10.2	7.4	3.5	1.0	2.0
2–4	10.0	19.9	18.2	2.9	8.9
5–9	7.6	13.2	32.3	12.4	29.2
10–14	5.6	5.8	13.9	26.7	35.0
15–19	8.0	6.0	5.1	29.1	14.1
20–24	14.9	8.5	4.0	9.8	3.6
25–29	16.1	14.4	4.8	5.0	1.6
30+	27.5	22.3	17.1	10.7	3.7

Notes. Data for rounds 1 to 3 reflect the mining work force tenure distributions except for the influence of selective participation. Round 4 was not a cross-sectional study but largely a follow-up group, and the tenure distribution reflects that. The 1986 survey data are projected statistics for coal miners underground and on the surface at underground mines in the bituminous and anthracite areas. They were derived from a Bureau of Mines mail survey of coal mine operators.[30]

Also included in Table 3 is a tenure distribution projected for the underground coal mining work force for 1986. This was derived from data collected from a mail survey of coal mine operators undertaken by the Bureau of Mines.[30] The data, which apply to both underground miners and surface workers at underground facilities in the bituminous and anthracite regions, were supplied on computer tape by the bureau. Because these data were rounded up to the nearest year, one year was subtracted to make them consistent with the radiological data, for which rounding down was performed. Based on the bureau's estimates, the round 4 tenure distribution clearly does not represent the general underground mining work force at that time. This is not surprising, given that round 4 participants represent a cohort followed from rounds 1 and 2.

Small Rounded Opacities

In every round of the NSCWP, a clear trend of increasing prevalence of CWP with tenure is evident (Figures 2 and 3). Round 4 tenure-specific rates of category 1 or greater small rounded opacities were about one-third those of round 1 (Figure 2), while rates of category 2 or greater opacities showed larger drops from round 1 to round 4 (Figure 3).

Large Opacities

Figure 4 provides information on the prevalence of progressive massive fibrosis. These data for large opacity prevalence are probably more prone to selection effects than are the data for small opacities, given that miners with severe CWP are more likely to leave mining for health reasons (and with compensation provided by the Federal Coal Mine Health and Safety Act ["Black Lung Act"] of 1969). There is a trend toward lower prevalences from round 1 through round 3, which probably reflects the effect of both lower dust exposures and loss of miners with progressive massive fibrosis from the work force. The prevalences at round 4 are similar to those at round 3. The reason for this is not clear although the increased participation rates at round 4 may be responsible. The round 4 data are currently under more detailed study, including an evaluation of 15-year incidence.

Standardized Rates

For each round, estimated summary statistics for small rounded opacity prevalence, obtained from the Bureau of Mines survey data[30] and standardized to the common tenure distribution, were derived for small rounded opacities of category 1 or greater and of category 2 or greater. These are shown in Table 4. They indicate a slight drop in prevalence from round 1 to round 2, an approximate halving in prevalence from round 2 to round 3, and a further drop from round 3 to round 4.

Small Combined Opacities

Although small rounded opacities have been more commonly associated

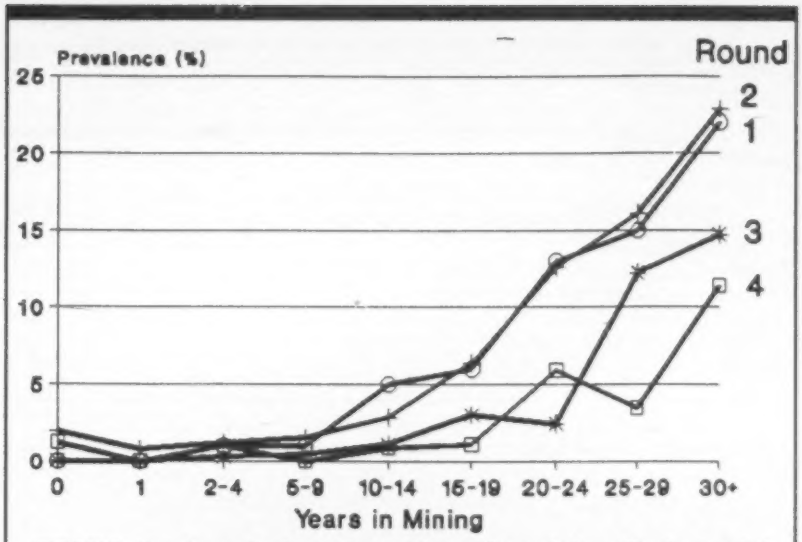

FIGURE 2—Prevalence of category 1 or greater small rounded opacities by round of the National Study of Coal Workers' Pneumoconiosis and by tenure group. Single reader at Round 1; median readings for other rounds.

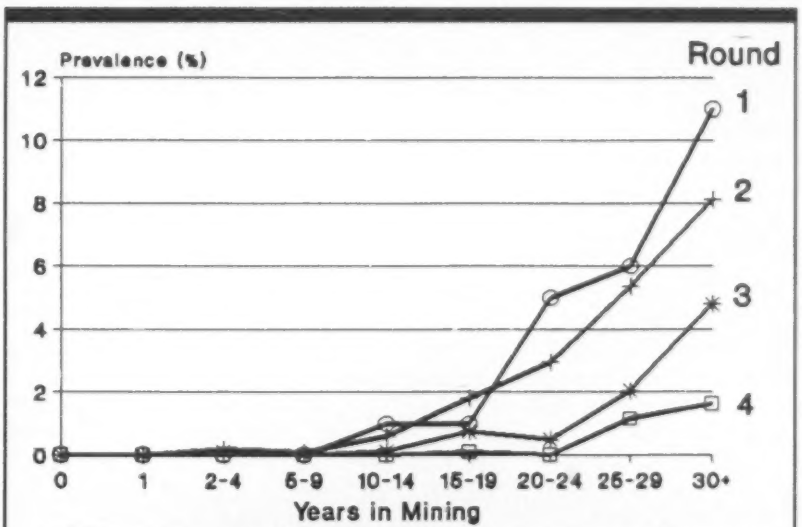

FIGURE 3—Prevalence of category 2 or greater small rounded opacities by round of the National Study of Coal Workers' Pneumoconiosis and by tenure group. Single reader at Round 1; median readings for other rounds.

with CWP, there is some evidence that small irregular opacities may also be associated with coal mine dust exposure.[31] For this reason, and because different readers sometimes report similar profusions yet differ on the predominant type of small opacity on chest radiographs, summary adjusted statistics for combined opacities are also shown in Table 4. These prevalences are somewhat higher, as expected, but do parallel the downward trends seen for small rounded opacities.

Discussion

The prevalences of CWP shown in Figures 2 to 4 and summarized in Table 4 reveal clear downward trends over time. Similar trends are evident in data from a large federal x-ray surveillance program for underground coal miners.[1] Both sets of data suggest that prevalences at round 4 were about a third of their levels at round 1. Reductions in reported prevalence of more severe categories of pneumoconiosis (e.g., category 2 or greater) were somewhat greater.

The observed trends occurred concurrently with reductions in dust exposure mandated by the 1969 Federal Coal Mine Health and Safety Act and recorded by the Mine Safety and Health Administration. According to the report by Parobeck and Jankowski,[32] respirable dust levels in US mines dropped from averages of about 6 mg/m^3 for face jobs in 1968 to 1969 to less than 1.5 mg/m^3 10 years later. Although there is evidence that the actual decline in dust levels may not have been as great as reported,[33,34] it is very likely that most underground coal miners experience lower exposures today than they did prior to passage of the 1969 Federal Coal Mine Health and Safety Act.

Although reductions in dust levels and other CWP prevention measures are the most likely reason for the declines in prevalence of radiological abnormality, there may be some degree of confounding with other effects, such as selective participation and exodus of miners with lung disease from the work force. Artifactual effects associated with x-ray reading, such as the use of different readers and international x-ray classifications systems, and possible changes in readers' perceptions over time may also be confounded with real trends in prevalence. It is difficult to assess how these factors may have influenced the results presented here. To obtain a clearer understanding of temporal trends in the prevalence and severity of CWP in coal miners, a study is planned that will involve the rereading of large numbers of chest radiographs selected from all four rounds of the NSCWP. This will be designed to control for potential confounding associated with these artifactual effects.

The Bureau of Mines survey data given in Table 3 indicate that the 1986 underground coal mining work force was fairly young, with most miners having worked fewer than 20 years in mining. As a consequence, use of this distribution for standardization leads to rates reflecting prevalence among the less experienced miners. If it is preliminary evidence on the efficacy of the current federal dust limit that is being sought, use of this distribution is very appropriate because, to date, only those with limited tenure have been working under the lower dust limits mandated by the 1969 act. However, use of this distribution does not lead to a fair picture of prevalence levels and changes among older miners. Simple averages of the tenure-specific rates for miners with 20 or more years of work in

mining indicate drops from 16.9% to 6.9% for category 1 or greater small rounded opacities, and from 7.1% to 0.9% for category 2 or greater small rounded opacities. As might be expected, the drops in prevalence (as measured by the ratios of the prevalences) are not so marked as those obtained for the summary rates in Table 4. This is probably because many of the older miners in round 4 had substantial lung dust burdens that were gained from exposures received before 1969.

Although reliance on only one reading from round 1 is a less than desirable strategy, it was considered unavoidable if data from that round were to be included in this report. Overall, it was felt that the round 1 data were sufficiently reliable to merit inclusion. Reasons for this were (1) the general consistency of the round 1 data with prevalence trends seen in the following three rounds; (2) the consistency of the prevalence trends in the present data compared with trends seen over the same period in coal miner surveillance data[1]; and (3) the similarity between the prevalences from round 1 and those from studies conducted prior to round 1 (medium and medium-low rank data in Figure 1).

One unexpected feature of the results in this report pertains to the Figure 2 tenure-specific data, which show the round 2 rates to be similar to those for round 1. A similar effect was evident over the same period elsewhere.[1] Some consider that this effect may be at least partially artifactual[3,5] and associated with differences in the standard reference films for category 1 that accompanied the 1968 and 1971 versions of the ILO classification. This authority and others (private communication) consider that films that would have been classified as category 0 using the 1968 classification (used at round 1) were more likely to be placed in category 1 under the 1971 x-ray classification (used during rounds 2 and 3). As a result, true declines in prevalence would be offset by apparent increases associated with the different ILO classification system used. However, clear declines in prevalence were seen over the same period for category 2 or greater small rounded opacities. Therefore, where no major effect associated with differences in the standard reference films has been suggested, the proposed explanation appears to have some merit.

Because round 4 was designed to be a follow-up study of participants from earlier rounds of the NSCWP, it was organized rather differently from the cross-sectionally based rounds 1 to 3. Hence, it may be incorrect to include its results with those from the other rounds to assess temporal trends in CWP prevalence. However, because ex-miners who left mining for health-related reasons are excluded from the round 4 results, because the analyses presented are adjusted for tenure, and because most of the ex-miners included left work in mining within a year or two of round 4, inclusion of the round 4 results is probably valid. Further support for their inclusion is provided by results from the surveillance program,[1] in which a similar temporal trend was seen for the same period.

The prevalence data given in this report clearly provide information useful for assessing the efficacy of the current federal dust control regulations in preventing occupational lung disease among underground coal miners. Because this information has its limitations, as noted above, an alternative approach to cross-sectional investigation is the longitudinal study, in which x-ray pairs for individual workers taken over suitable intervals of time are read together under controlled conditions using the same readers and classification system. Such studies have already been undertaken[8,9] and indicate an incidence rate of category 1 or greater small rounded opacities of about 0.5% over 10 years among miners with category 0 on initial examination. This finding is consistent with sharply reduced prevalence rates predicted for the future compared with past levels. Additional longitudinal analyses that include both miners and ex-miners are in progress. Among other things, these will provide needed information on workers who may have left coal mining work because of ill health.

Overall, the results presented here reveal a clear downward trend in the prevalence of CWP in US miners. It seems highly likely that this trend represents a real decline in CWP prevalence, particularly because a similar downward trend has been observed over the same period in data from large numbers of underground coal miners participating in a federal x-ray

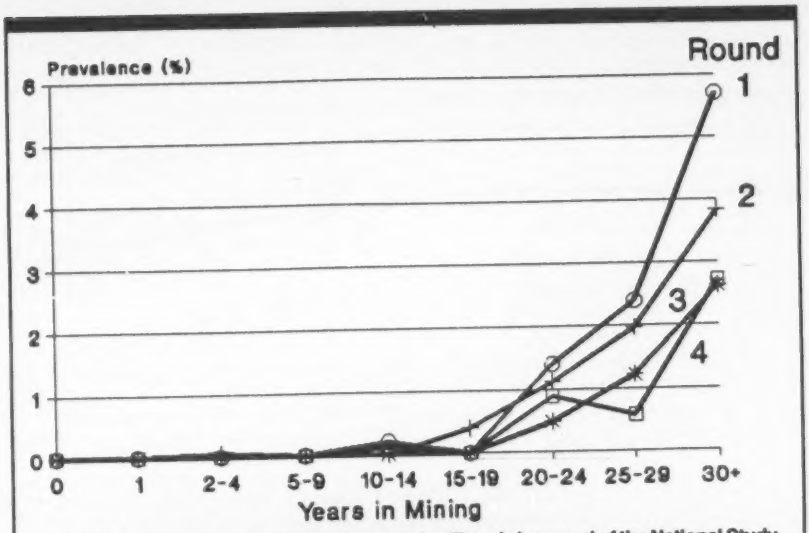

FIGURE 4—Prevalence of progressive massive fibrosis by round of the National Study of Coal Workers' Pneumoconiosis and by tenure group. Single reader at Round 1; median readings for other rounds.

TABLE 4—Summary Coal Workers' Pneumoconiosis Prevalence Statistics from the National Study of Coal Workers' Pneumoconiosis, Based on Small Rounded and Small Combined Opacities, Category 1 or Greater (1+) and Category 2 or Greater (2+), and Adjusted to Common Tenure Distribution

		Adjusted Summary Prevalences, %			
	Category	Round 1	Round 2	Round 3	Round 4
Rounded opacities	1+	4.5	4.1	1.8	1.3
	2+	1.2	1.0	0.4	0.1
Combined opacities	1+	6.6	5.1	3.6	2.3
	2+	1.5	1.2	0.5	0.3

examination program.[1] The findings from this report, coupled with those from longitudinal studies,[8,9] suggest that substantial progress has been made in reducing the prevalence of CWP in underground coal miners. However, owing to the limited periods of study and to other methodological difficulties, these findings should not be taken to imply that coal mining is now risk free with respect to CWP. Furthermore, these results provide no information on dust-induced lung diseases other than pneumoconiosis (e.g., chronic bronchitis and airways obstruction). Continued study of both pneumoconiotic and other lung diseases is necessary to ensure adequate protection of the respiratory health of underground coal miners. □

Acknowledgments

Thanks are due to Barbara Bonnett for help in preparation of the figures and in other programming, and to the many who have helped in preparing and reviewing the manuscript.

Surveillance Data on US Coal Miners' Pneumoconiosis, 1970 to 1986

Michael D. Attfield, PhD, and Rochelle B. Althouse, BS, MS

ABSTRACT

Objectives. Statistics on prevalence of pneumoconiosis among working underground coal miners from data collected as part of a large national radiographic surveillance program between 1970 and 1986 are presented. The main intent was to examine the time-related trend in prevalence over this period, which coincides with historically low dust levels mandated by federal act.

Methods. Tenure-specific prevalence rates and summary statistics derived from them for four consecutive time intervals within the 16-year period were calculated and compared.

Results. The results indicate a reduction in pneumoconiosis over the life of the program. This trend is similar to that seen in epidemiologic studies undertaken concurrently.

Conclusions. Although low participation in the surveillance program and other problems complicate the findings, it appears that reductions in dust exposure mandated by federal act in 1969 have led to lower prevalence of pneumoconiosis among underground coal miners. (*Am J Public Health.* 1992;82:971–977)

Introduction

As part of a lung disease prevention program mandated by the Federal Coal Mine Health and Safety Act,[1] radiographic examinations of the chest are made available to underground coal miners every 5 years. If an x-ray shows certain signs of coal workers' pneumoconiosis (CWP), a miner is given the right to work in a low-dust environment. This procedure, combined with a general control of dust levels mandated by the law, is intended to prevent or slow down the progression of CWP in underground miners and thus reduce the risk of progressive massive fibrosis (PMF).

The administration of these x-rays and of related quality control procedures occurs under the Coal Workers' X-ray Surveillance Program (CWXSP), which is overseen by the National Institute for Occupational Safety and Health (NIOSH). Although primarily serving as a medical monitoring program for underground miners, the CWXSP also provides data that are pertinent to assessing CWP prevalence and to determining the effectiveness of the mandated dust control measures in reducing and eliminating CWP.

This paper provides statistics on the more than 250 000 x-rays collected in the CWXSP since 1970. Information by tenure group is provided, as are various adjusted summary rates reflecting prevalence of CWP among program participants. To permit valid comparisons of data for different periods, details on operational changes are given.

Operation of the CWXSP

Past and present regulations governing the operation of the CWXSP are described in Title 42 of the Code of Federal Regulations.[2–5] In summary, the program is overseen by NIOSH, which, by referring to records on active mines maintained by the Mine Safety and Health Administration, notifies mine operators when its employees are due to be examined. The operator must then file a mine examination plan, which provides information on when and where miners can get their x-rays and on who will do the initial x-ray reading. On receipt of this information, NIOSH determines whether the designated medical facilities and readers are qualified, among other requirements. If a mine operator does not supply a plan, NIOSH prepares one and notifies the operator.

After a plan is approved, it must be posted at the mine site when the time comes due for the examinations. Miners may then present themselves to the designated facility to get an x-ray on their own time and at no cost to themselves. While the miner is at the facility, a brief occupational history is taken using a standard form. The x-ray is classified by the first reader (usually an A reader, but sometimes a B reader [see below]), who typically resides locally. After this, the x-ray film, form, and initial reading must be sent to NIOSH; the x-ray is then sent to a B reader for a further reading. If the two readings are sufficiently similar (definitions of agreement have varied somewhat over time but basically consist of agreement within the same major category of

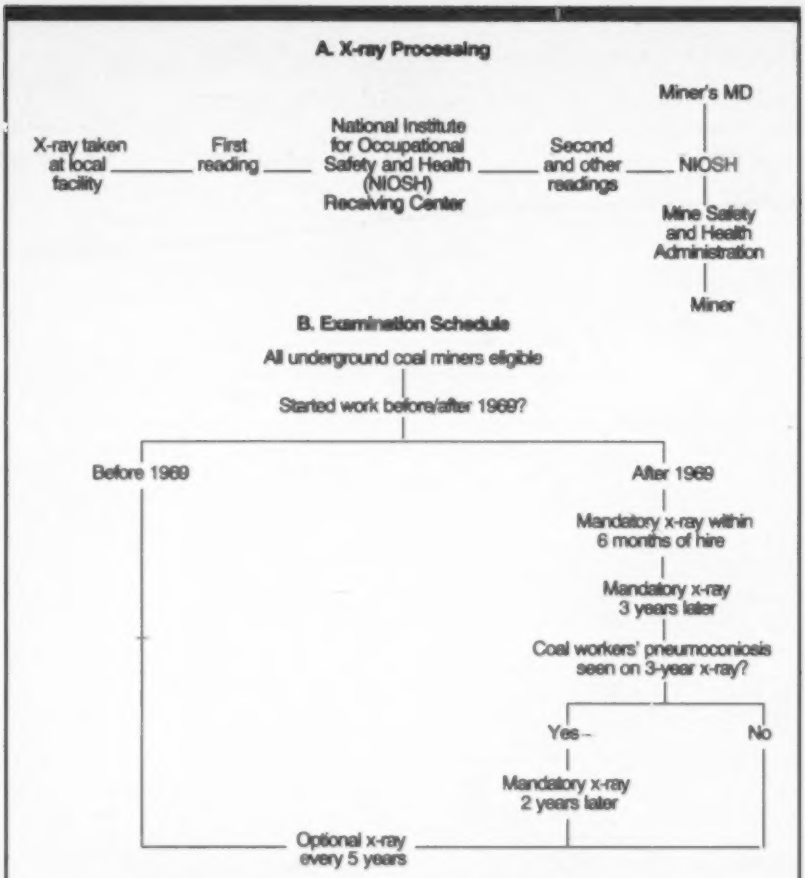

FIGURE 1—Broad processing scheme for x-rays in the Coal Workers' X-ray Surveillance Program.

small opacity profusion), the "final determination" is set equal to the maximum profusion category of the two. If there is greater disagreement than this, further readings are made until sufficient agreement is obtained. The miner is awarded the right to work in a job with a dust exposure of 1 mg/m^3 or less if the final determination is category 1/0 or greater. All program participants have the opportunity to have the results of their x-ray readings (negative or positive) sent to their personal physician. See Figure 1A for details of the x-ray processing.

As a part of a quality control program, the x-ray readers who participate must satisfy certain tests of their competence. Currently, both A and B readers are certified by NIOSH. To become an A reader, the applicant must either attend a special NIOSH seminar or submit six correctly classified chest x-rays. B readers must have passed a special test administered by NIOSH and must undergo regular reexamination to maintain certification.[6] Hundreds of readers have been involved in the program since its inception. As a result, the statistics given in this report should not, in the main, be influenced unduly by individual idiosyncrasies among the readers.

All coal miners working at underground mines are eligible for the periodic x-rays. Currently, miner participation is optional except for new miners, who must have an x-ray within 6 months of starting work at an underground mine and another x-ray 3 years later. A third x-ray, to be taken 2 years later, is mandatory if the second shows signs of CWP. Figure 1B shows the examination schedule schematically.

Between August 1970 and August 1981, the CWXSP was organized into three so-called rounds. Each round was made up of two parts: an initial period when all active mines had to complete examination plans, and a follow-up period when x-rays—mostly those for new miners and for others receiving mandatory x-rays—were being taken. However, logistical problems incurred by the large influx of x-rays at the start of each round led NIOSH to discontinue this administration procedure. Instead, to smooth out processing, mine plans were filed on a continuous basis after 1981. In this report, for convenience, the period between August 1981 and December 1986 will be referred to as round 4, although it is not a round in the same sense as were the previous three. Details pertinent to each round are given in Table 1.

Film Readings

The results presented here are confined to data based on the first and second x-ray readings. (Results are not given for the final determinations because the procedures by which they were obtained differed between the rounds.) At least two readings were made on the films from rounds 1, 3, and 4. Because of logistical problems at round 2, the decision was made not obtain a second reading if the first reading had been made by a B reader (10% of all films). In rounds 3 and 4, the second reading was always made by a B reader, but both A and B readers performed the first reading. Three sets of x-ray standards were used over the four rounds: the Union Internationale Contre le Cancer (UICC)/Cincinnati standards of 1968[7] (round 1), the 1971 International Labour Office (ILO) standards[8] (rounds 2 and 3), and the 1980 ILO standards[9] (round 4). Results are presented on prevalences of small rounded and small combined opacity profusions of progressive massive fibrosis. (For details pertaining to the definition of CWP and the derivation of small rounded opacity scores, see the report in this Journal on epidemiological findings.)[10]

In the following analysis, there are fewer readings than participants owing to the unavailability of data for films said to be unreadable. In some cases, multiple films for the same person were available within the same round; in these cases, only readings of the last film are included.

Results

The following analysis provides information on tenure-specific prevalences among the participants, and on summary statistics computed to facilitate the comparison of prevalences over the different rounds.

Tenure Distribution Data

Table 2 provides detailed information on the tenure distribution of participants at each round. Occupational history information was obtained from the miners by

interview at the time of examination. Note that the data from each round are probably weighted toward younger miners; this is owing to the dual mandatory/voluntary nature of the program. New miners, who must have initial and 3-year x-rays, tend to be younger. The experienced miners, who are generally older and not required to obtain regular x-rays, have participated less in the program. As a result, the tenure distributions of CWXSP participants might be expected to be different from those that would have resulted from a census of the work force held at the same time.

Furthermore, selective participation may have occurred, with the healthier miners having been more likely to choose to attend. Lastly, the age structure of the mining work force has been changing dramatically since 1969. In particular, there was a large reduction in the average age between 1969 and 1979 as older men retired from the generally elderly work force, and young men were hired to fill the deficit and to man mines newly opened or expanded in response to the energy crisis of the mid-1970s.

The table also includes a projected tenure distribution for the 1986 work force for underground and surface workers at underground coal mines; this distribution was derived from a mail survey of coal mine operators.[11]

TABLE 1—Background Information on Each Round

	Round 1	Round 2	Round 3	Round 4
Dates	1970–1973	1973–1978	1978–1981	1981–1986
X-ray classification system	1968[7]	1971[8]	1971[8]	1980[9]
Number of participants	77 756	122 625	63 519	40 634
Average total population in underground coal mining employment	103 000	128 000	144 000	110 000

Note. Work force estimates are from MSHA reports, such as that for 1988.[10]

TABLE 2—Tenure Distributions for Miners Who Attended the Four Completed Rounds of the Coal Workers' X-ray Surveillance Program and for Those Included in the 1986 Survey of Coal Miners[11]

Tenure in Mining Group	% Round 1 Miners (n = 71 404)	% Round 2 Miners (n = 107 031)	% Round 3 Miners (n = 58 282)	% Round 4 Miners (n = 34 953)	% 1986 Survey Miners[a] (n = 78 741)
0[b]	22.1	46.7	24.9	17.1	2.0
1	7.4	7.2	6.4	3.5	2.0
2–4	11.9	14.8	20.7	16.2	8.9
5–9	9.4	10.8	24.3	28.9	29.2
10–14	6.2	4.4	9.1	19.8	35.0
15–19	6.6	2.9	3.7	6.6	14.1
20–24	10.2	2.8	2.6	2.6	3.6
25–29	8.8	4.0	2.2	1.6	1.6
30+	17.8	6.5	6.1	3.7	3.7

[a]The tenure figures for the 1986 survey were computed from data supplied by the Bureau of Mines. Because the original data were rounded up to the nearest integer, 1 year was subtracted from the tenure to make the data consistent with the radiological data (in which the figures were rounded down).
[b]The zero tenure group includes all those with less than 1 year.

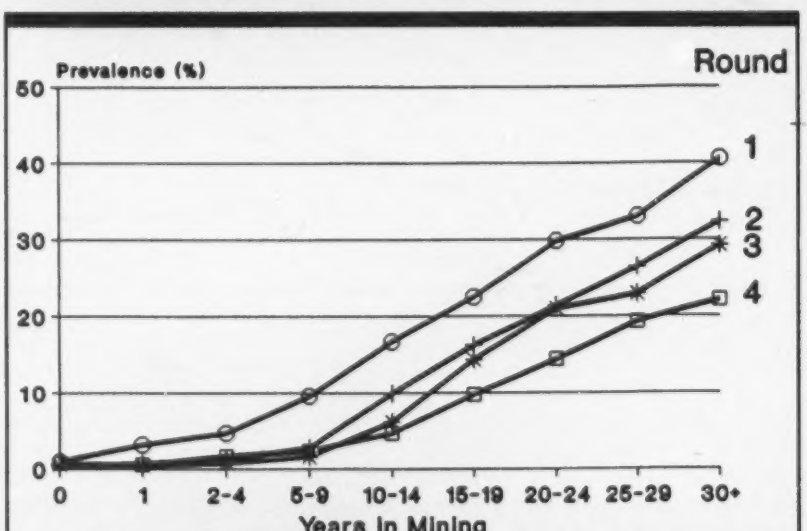

FIGURE 2—Tenure-specific prevalences of category 1 or greater small rounded opacities by round of the Coal Workers' X-ray Surveillance Program, based on the first readings only.

Tenure-Specific Prevalences: Small Rounded Opacities

Figures 2 and 3 show tenure-specific prevalence rates of category 1 or greater small rounded opacities for the first and second readers, respectively. Comparison of these tenure-specific rates across rounds reveals several interesting points. The first readings (Figure 2) show a consistent decline in prevalence over all four rounds in virtually every tenure group. In comparison, the second readings (Figure 3) reveal higher prevalences in round 2 for longer-tenured miners; otherwise, the trends are similar. Comparison of the two figures reveals that, at all four rounds, the second readers tended to report fewer cases of abnormality than the first readers, an effect that is most obvious in round 1.

Figures 4 and 5 provide corresponding statistics for category 2 or greater small rounded opacities. Both the first and second readings show a consistent reduction in prevalence over time; however, the general prevalence levels are higher for the first readings.

Summary Statistics for Small Rounded Opacities

The data given in Figures 2 through 5 were used to derive certain summary statistics. First, summation of the products of tenure-specific prevalence shown in those figures with the tenure distribution proportions from Table 2 for each round gave rise to crude prevalence rates for all participants by round (see Table 3). How-

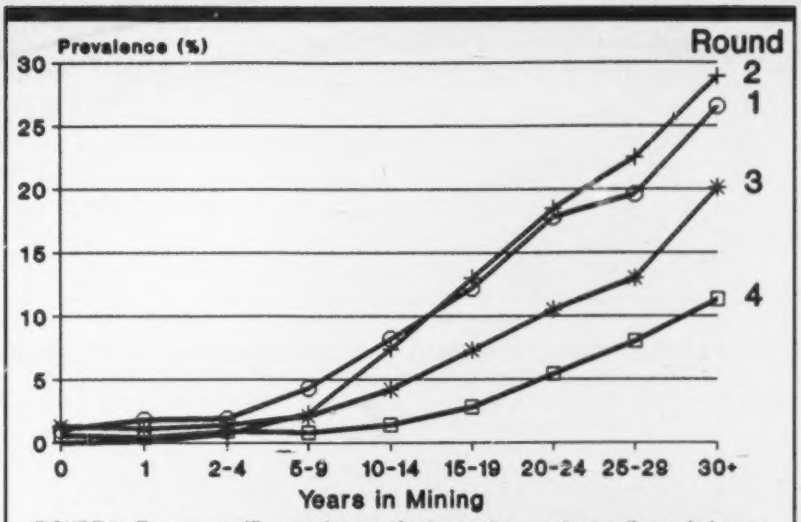

FIGURE 3—Tenure-specific prevalences of category 1 or greater small rounded opacities by round of the Coal Workers' X-ray Surveillance Program, based on the second readings only.

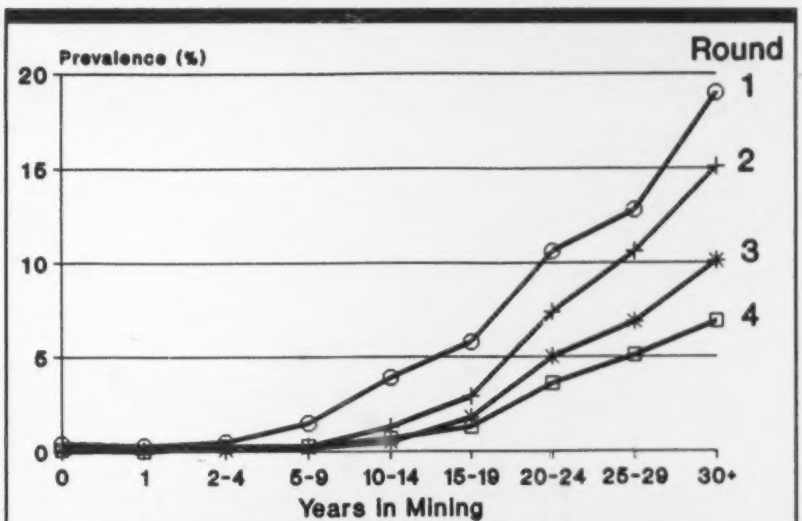

FIGURE 4—Tenure-specific prevalences of category 2 or greater small rounded opacities by round of the Coal Workers' X-ray Surveillance Program, based on the first readings only.

ever, these rates are naturally heavily weighted by the zero tenure group and, to some extent, by the 3-year x-rays. Thus, to eliminate the spurious and misleading weighting caused by the mandatory preemployment and 3-year x-rays, the above approach was modified by omitting the 0- to 4-year tenure group from the summation and adjusting to account for the fact that the tenure proportions no longer add to 100%. Not surprisingly, these statistics are all larger than the crude rates (see Table 3). They tend to reflect the influence of changes in both employment patterns and dust control, while removing the effect of the mandatory films.

The question of whether dust control brought about a reduction in prevalence after 1969 was tackled by standardizing the rates for each round to a constant tenure distribution. A summary statistic was formed by multiplying tenure-specific prevalences from Figures 2 through 5 for each round by the proportions of miners in the tenure groups given by the Bureau of Mines survey.[11] Note that these statistics were generated for interround comparison and should not be regarded as estimates of prevalence at any particular round of the CWXSP, except perhaps the fourth. Other tenure distributions could obviously have been used for standardization.

Overall, the summary statistics reveal that the first readers consistently reported more abnormality than did the second readers. The summary rates also show that, once the weighting effect of the new miners is removed (e.g., by restricting the calculations to those miners with 5 or more years of tenure), the prevalences show a much more gradual and uniform drop from round 1 to round 4. Hence, large temporal changes in tenure distribution were clearly responsible for large variations in the crude summary prevalence statistics. Lastly, standardization to a common tenure distribution leads to the smallest drop in prevalence from round 1 to round 4 of the three summary statistics, although clear downward trends over the rounds are still evident.

Small Combined Opacities

Although most research into the radiographic appearances of CWP has concentrated on rounded opacities, there have been some recent indications that irregular opacities are also associated with dust exposure.[12] For completeness, the prevalences of both rounded and irregular opacities (i.e., combined opacities) have been tabulated, with the resulting adjusted rates shown in Table 4. As expected, the rates are all higher but otherwise follow the same trends seen in Table 3.

Prevalence of Large Opacities

Standardization for tenure was not undertaken on the data for large opacities because there were too few cases. However, tenure-specific prevalences of progressive massive fibrosis by round and reader are given in Figures 6 and 7. The data exhibit similar tendencies to those seen for small opacities—namely, a rise in prevalence with tenure and a trend toward lower prevalences of disease at the later rounds.

Participation

Participation is obviously an important issue with these data: if it is not 100%, self-selection and, hence, bias might be suspected. Unfortunately, assessing bias in the CWXSP to any detailed extent is very difficult owing to a paucity of data by age, region, etc., on the baseline population of miners eligible for the program at any time.

Some very rough rates of participation pertinent to miners eligible for the vol-

untary aspect of the program were derived. This was done by dividing the numbers of examined miners with 1 or more years of tenure at each round by average work force estimates applicable to each round obtained from annual Mine Safety and Health Administration reports on injuries, such as that for 1986.[13] The results indicate that participation of miners with 1 or more years of tenure at rounds 1 through 4 was 50%, 44%, 32%, and 30%, respectively.

Some indication of tenure-specific participation can be gained for round 4 of the CWXSP by using some Bureau of Mines survey data[11] (shown in Table 2 of this report). Tenure-specific participation rates based on these data were 44%, 25%, 21%, 32%, 44%, and 44% for the 5–9, 10–14, 15–19, 20–24, 25–29, and 30+ groups, respectively. It is interesting that participation appears to improve among miners with longer tenure in mining.

Comparison with Epidemiological Data

Undertaken concurrently with the coal miner surveillance program was a large-scale, nationwide epidemiological study of underground coal miners. Results from that research are described in a companion report.[10] Summary rates of small opacity profusion standardized to the Bureau of Mines survey tenure distribution were derived (see Tables 3 and 4); these reveal trends similar to those noted here for the surveillance data, although the reported prevalences appear to be generally lower.

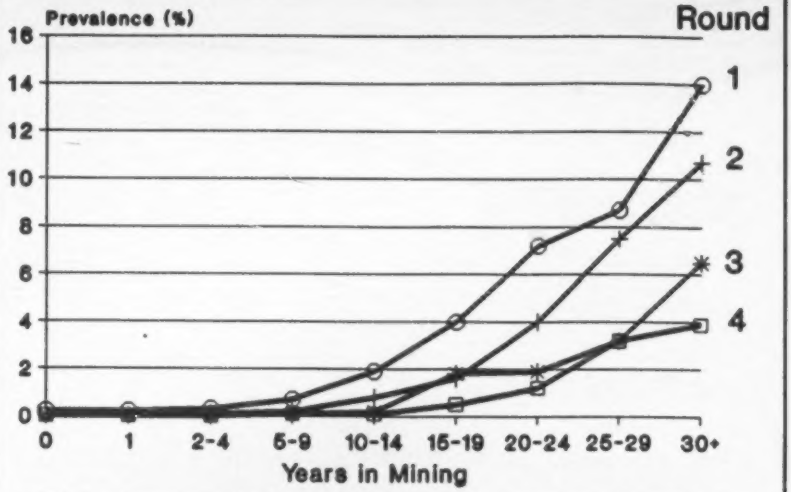

FIGURE 5—Tenure-specific prevalences of category 2 or greater small rounded opacities by round of the Coal Workers' X-ray Surveillance Program, based on the second readings only.

Discussion

The information reported here reveals a clear downward trend in CWP prevalence among program participants over time. The decline parallels that observed over a series of medical surveys undertaken as part of a long-term epidemiological study of US underground coal miners[10] (see Tables 2 and 3 of this report). Both sets of data suggest that prevalences of category 1 or greater small opacities at round 4 (1981 to 1986) were about one-third of their levels at round 1 (1970 to 1973). Reductions in reported prevalence of category 2 or greater small opacities were somewhat larger.

These reductions in prevalence coincide with lower dust exposure limits mandated by the 1969 Federal Coal Mine Health and Safety Act.[1] Under the regulations promulgated by that legislation, permissible airborne respirable dust concentrations in underground coal mines are currently limited to 2 mg/m^3. This contrasts to levels of 6 mg/m^3 or more existing before 1969.[14] Documented trends of dust concentrations in underground mines indicate a substantial decline over the 10 years from 1968,[15] although there is some evidence that the reductions have not been as great as reported.[16,17]

Because the 1986 underground coal mining work force was fairly young, use of this distribution for standardization leads to rates reflecting prevalence among the less experienced miners. This is appropriate if preliminary evidence on the efficacy of the current federal dust limit is being sought, for it is only those with limited tenure who have, to date, been working under the lower dust

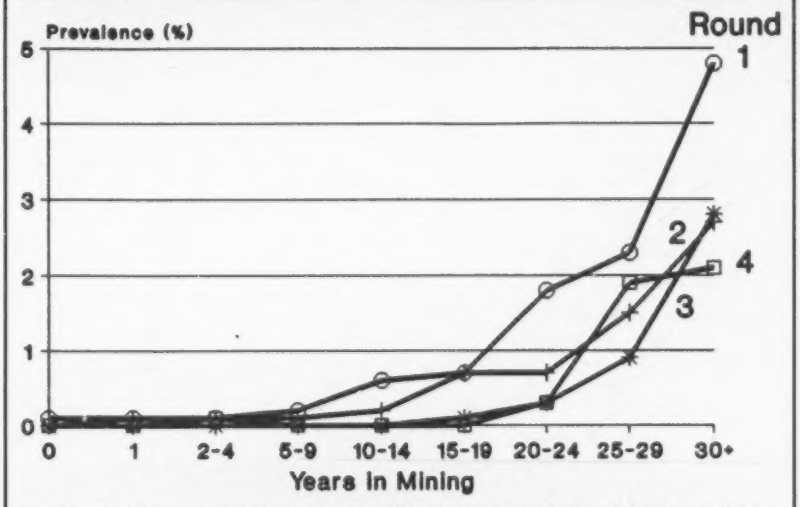

FIGURE 6—Tenure-specific prevalences of large opacities by round of the Coal Workers' X-ray Surveillance Program, based on the first readings only.

limits mandated by the 1969 law. However, this distribution is inadequate for estimation and comparison of prevalence levels and changes in older miners. Simple averages of the tenure-specific rates for miners with 20 or more years of work in mining indicate drops for category 1 or greater small rounded opacities from 34.5% to 23.3% for the first readers and from 12.1% to 5.7% for the second readers. Corresponding figures for category 2 or greater small rounded opacities were from 24.4% to 8.2% for the first readers and from 6.2% to 2.2% for the second readers. As might be expected, the reductions in prevalence (as measured by the ratios of the prevalences) are not so marked as those obtained using the 1986 work force distribution (Table 3, common tenure distribution). This may be because many of the older miners in round 4 had substantial lung dust burdens that were gained from exposures received before 1969.

In general, the prevalences estimated from the surveillance data are greater than those from the epidemiological study. It is not clear why this occurred. Possible reasons for the difference may lie with x-ray reader effects or with systematic differences in prevalence associated with the types and sizes of the mining operations feeding into the two programs. The epidemiological study has always involved large operations, which may have better dust-control procedures and thus lower levels of CWP than the smaller mines. Smaller mines form a large part of the input to the CWXSP.

Prior reports on the CWXSP have generally concentrated on certain restricted aspects of the data.[18-21] The findings from those papers are essentially the same as those presented here and are not discussed further.

There are obviously many problems in interpreting data from successive cross-sectional surveys. These include exodus of workers with ill-health, self-selection bias, changes in the x-ray classification standards, and interreader variability. There is also the possibility that readers' perceptions of CWP have been changing over time. Some reading exercises involving large amounts of film are planned. These should provide more reliable information on trends in prevalence of CWP in underground coal miners.

Longitudinal study approaches can control for many of the factors that interfere with interpreting cross-sectional data. In such studies, a specific cohort of workers is followed over time, with the x-rays being read at one time in a controlled reading environment. Althouse et al.[22] conducted one such study using films from the CWXSP and looking at x-ray changes over 10 years in new miners. Of 1825 miners studied, a net total of 15 developed category 1 opacities from category 0; no category 2 or greater readings were reported. While these reported incidence levels are encouraging, they should be regarded as only preliminary; further studies are needed owing to the relatively short observation period and to the fact that CWP is often not manifested until after more than 10 years of exposure.

In conclusion, despite methodological limitations, the results presented here demonstrate a temporal reduction in prevalence of CWP that is consistent with results from concurrent epidemiological investigations and coincides with reductions

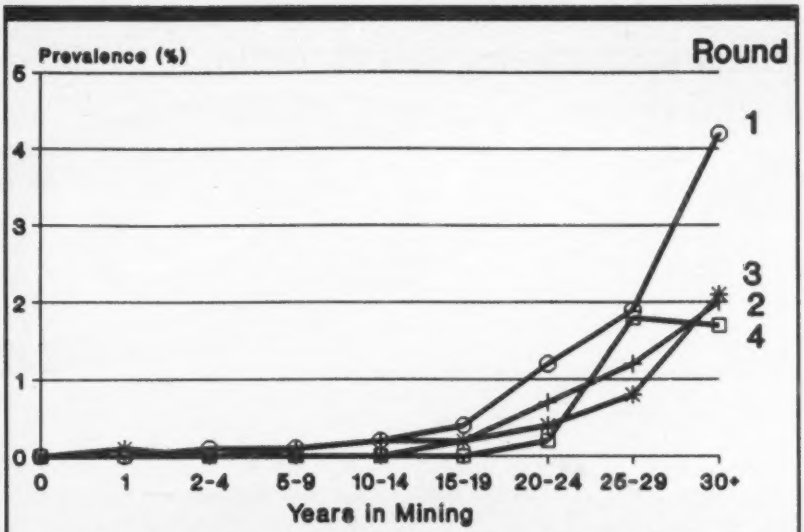

FIGURE 7—Tenure-specific prevalences of large opacities by round of the Coal Workers' X-ray Surveillance Program, based on the second readings only.

in dust levels mandated after 1969. Continual vigilance in dust control is necessary to ensure that these gains are maintained and, it is hoped, advanced. Emphasis on dust control is especially important with regard to the increasing use of mining techniques that tend to cause greater dust generation, such as longwall methods.[23] In addition, the implications of coal mine dust exposure for lung diseases other than pneumoconiosis must be fully determined. □

British Data on Coal Miners' Pneumoconiosis and Relevance to US Conditions

Michael D. Attfield, PhD

ABSTRACT

Objectives. The current primary federal dust standard for US underground coal miners of 2 mg/m^3 respirable dust is based on British epidemiological information on exposure-response derived in 1969. Since then, much new information has become available. This paper reviews and compares the available information as it relates to the US mining situation.

Methods. Recent exposure–response information on pneumoconiosis and dust exposure derived by British researchers was employed to estimate working-life risks of pneumoconiosis for miners exposed to 2 mg/m^3.

Results. It is estimated that close to 9% of underground coal miners who work for 40 years in a 2 mg/m^3 environment would develop pneumoconiosis (category 1 or greater). Progressive massive fibrosis would develop in 0.7%.

Conclusions. There are unresolved questions relating to the validity of extrapolating findings on British mines and miners to the US and also in predicting disease levels at the low end of the dust exposure spectrum. Given the data available, current information suggests miners who are employed for a working lifetime at the current federal dust limit of 2 mg/m^3 are still at risk of developing pneumoconiosis. (*Am J Public Health.* 1992;82:978–983)

Introduction

It was not until 1969 that a nationwide limit was set on the level of dust to which US underground coal miners could be exposed. In that year, the Federal Coal Mine Health and Safety Act was passed.[1] This mandated that a dust standard of 3 mg/m^3 be imposed, with a reduction to 2 mg/m^3 to come into force in December 1972. (There is currently a requirement that dust levels be reduced further if the mine dust contains more than 5% quartz.) The intention was to prevent premature death and disability associated with coal workers' pneumoconiosis (CWP).

Owing to the lack of adequate epidemiological information on US underground coal miners at the time, those responsible for the law relied heavily on findings from overseas studies, primarily some interim results from Britain. Over the 23 years that have elapsed since the passage of the act, the British researchers have pursued their analyses further and developed more refined analyses. The purpose of this paper is to review both the initial and later results from Britain, and to discuss their applicability to the US underground coal mining situation.

After some preliminary background information, the paper outlines the scientific basis of the current federal 2 mg/m^3 standard. It then reviews the epidemiological findings that have been published since 1969 on British miners. Finally, it discusses some issues that involve the application of these results to US coal miners.

Note that this report is concerned only with CWP as determined through examination of chest x-rays; it does not deal with questions relating to the utility of the current dust standard in preventing other diseases, such as bronchitis and emphysema. Furthermore, no attempt has been made here to assess the efficacy of current disease-prevention measures through examination of CWP prevalence rates in US coal miners observed since 1969. Prevalence information is available in two reports: one on data from a national x-ray screening program known as the Coal Workers' X-ray Surveillance Program,[2] and one on results from a large continuing epidemiological study called the National Study of Coal Workers' Pneumoconiosis.[3]

Background

Coal mining existed in the United States for many years before it was accepted that many coal miners were suffering from occupational lung disease; and although silicosis was known to occur in some miners, the inhalation of coal dust with a low silica component was often thought to be harmless or even beneficial.[4] However, the accumulation of medical evidence to the contrary eventually led in 1969 to the enactment of federal regulations for the control of coal mine dust.

CWP is divided into two disease states: simple CWP and complicated pneumoconiosis (also called progressive massive fibrosis, or PMF).[5] In living coal miners, simple and complicated CWP are both almost always detected through examination of chest x-rays. The severity of simple CWP is measured in terms of the profusion of opacities seen on the x-ray

and is recorded according to major categories (0, 1, 2, or 3), with each category being divided into three subcategories depending on the adjacent major category (e.g., major category 2 is divided into 2/1, 2/2, and 2/3). In this report, the emphasis is on rounded opacities (types p, q, and r), although recent evidence also suggests a relationship between irregular-shaped opacities (types s, t, and u) and coal dust exposure.[6] PMF is defined by the presence of one or more pneumoconiotic opacities of at least 1 cm in diameter. Miners who have simple CWP are at greatly increased risk of developing PMF, and this risk increases with category of simple CWP.[7]

In addition to the imposition of a dust limit, the federal act provided for a complementary radiographic screening program to identify miners who, for reasons of overexposure or individual susceptibility to dust, showed signs of CWP. Such miners are given the option of working in a low-dust (1 mg/m^3) environment while retaining their pay and benefits.

British Studies of CWP and Dust Exposure

British studies of CWP and other lung diseases associated with coal mining began in 1952. The principal program of investigation was the Pneumoconiosis Field Research (PFR).[8] In the PFR, coal miners working at mines located in all of Great Britain's major coalfields were medically examined at roughly 5-year intervals until the 1980s. Moreover, industrial hygienists were stationed at all the mines, their purpose being to assess the dust exposures of all miners prospectively as the study progressed. A systematic and intensive program of dust sampling was undertaken on all occupational groups, and the resulting mean dust concentrations were eventually linked with job tenure information gathered on each miner. Finally, respirable dust exposures that were developed for each miner were correlated with indices of lung disease in various studies, some of which are the subject of the following discussion.

The PFR must rank as one of the best conceived and managed epidemiological studies. Its features are a large number of subjects studied (initially 35 000 in 25 mines); continuous efforts to standardize data collection techniques and to minimize all sources of variability; a prospectively based program of dust exposure assessment, which was undertaken independently of any compliance sampling and was operated according to a scientifically designed plan of dust sampling; the collection of detailed time records of work performed by each miner; and excellent participation by miners in the study.

Basis for the Current Federal Dust Standard

In 1969, when the Federal Coal Mine Health and Safety Act was enacted in the United States, prevention of the disabling disease PMF was naturally one of its principal objectives. However, no information existed at that time that directly linked the degree of dust exposure to the risk of developing the disease. Nevertheless, two other important pieces of knowledge of relevance to this problem were available.

First, it was known that the risk of developing PMF was considerably greater among miners who had advanced simple CWP, such as category 2 or 3 (see Figure 1).[7] The abrupt rise in PMF risk associated with the higher categories of simple CWP suggested that PMF could be largely eliminated if progression to those categories could be prevented. Hence, it appeared desirable to limit the dust to a level where progression of miners to category 2 or greater simple CWP did not occur.

Second, based on data from the PFR, a curve had recently been developed, which related the risk of developing simple CWP category 2 or greater over 35 years to average dust concentration (Figure 2).[9] This curve was not derived from observation of incidence over that period but was actually extrapolated from results of a 10-year study, the Interim Standards Study (ISS).[10] From the 35-year curve, it was possible to identify the level of dust that would lead to any given degree of incidence of category 2 simple CWP or greater. Examination of the curve indicated that an exposure to 2 mg/m^3 coal mine dust would lead to zero incidence. Hence, it was argued, if exposures were kept to 2 mg/m^3 or below, miners would not progress to category 2 and thus would never get to be at high risk of developing PMF. It was on this basis that the federal standard was set at 2 mg/m^3. The Coal Workers' X-ray Surveillance Program was intended as a backup prevention strategy to identify those workers who might develop CWP despite dust control, and to enable such workers to work from then on in a low-dust environment.

Recent Information from the PFR on Exposure-Response for CWP

Although the strategy of preventing PMF through prevention of severe simple CWP was a reasonable course of action in 1969, given the lack of information that existed then on a direct relationship between PMF and dust exposure, it has a basic weakness. This was revealed in a

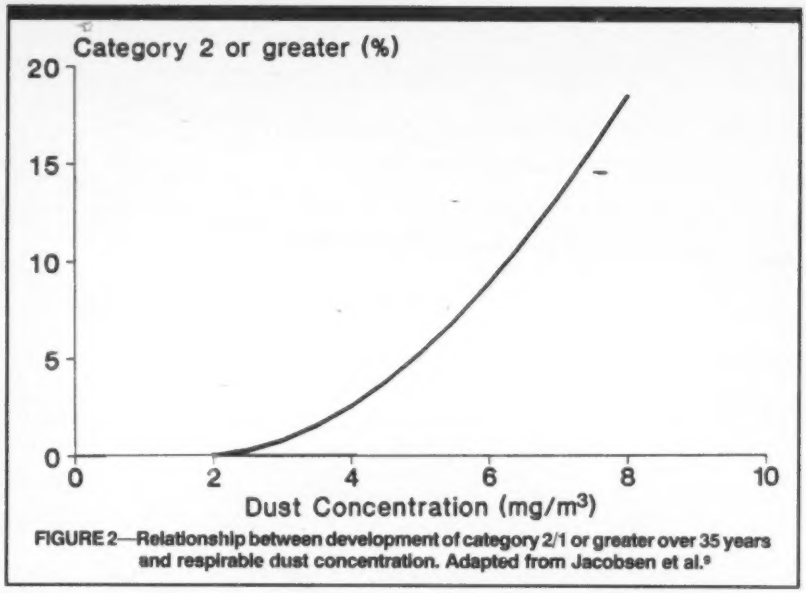

FIGURE 2—Relationship between development of category 2/1 or greater over 35 years and respirable dust concentration. Adapted from Jacobsen et al.[9]

series of articles that examined factors connected with the incidence of PMF.[11–14] The reports indicated that, contrary to Cochrane's findings,[7] the risk of PMF appeared somewhat lower for miners with categories 2 and 3 simple CWP but was rather higher for those with category 1. Because many more miners get category 1 CWP compared with those who get category 2 or 3, this implies that prevention of category 2 or greater would not eliminate the risk of getting PMF. In this respect, Shennan et al.[12] found that half the cases of PMF occurring in British miners over a 4- to 5-year period in the late 1970s were seen in miners who had category 0 or 1 at the initial examination. These findings suggested the need for an alternative approach to the prevention of PMF.

This new strategy was provided in the form of a curve linking PMF incidence directly to levels of dust exposure reported in 1985.[15] This curve was derived from data collected from 1959 to 1977 on over 30 000 British coal miners. Five-year estimates of the risk of PMF attack were obtained based on age and dust exposure; these were then compounded into 35-year predictions for various dust levels. The resulting curve indicated that an exposure to 2 mg/m^3 dust was associated with about a 1% risk of PMF. That is, 1 out of every 100 miners who worked for 35 years in an atmosphere containing 2 mg/m^3 of coal mine dust would be expected to develop PMF.

Although the above results suggest that coal miners who work for 35 years in a 2 mg/m^3 environment may be at risk of PMF, it should be noted that the analysis did not take into account the effect of secondary preventive measures—namely, x-ray surveillance and job transfer. In theory, people who exhibit early signs of CWP and then transfer to a low-dust environment should reduce their risk of progressing to a higher category of simple CWP and thus lower their chance of contracting PMF. To explore the effect of both primary and secondary measures on disease incidence in US coal miners, PFR researchers prepared a special analysis.[16] Their object was to determine what the incidence of PMF would be if a miner were to start work at age 18 and work until age 58 (a typical retirement age in US coal miners) in an atmosphere containing 2 mg/m^3 of coal mine dust, with transfer to a 1 mg/m^3 environment for those miners who were found by x-ray surveillance to have CWP category 1 or greater.

Latest Predictions of CWP Risk

Full details of the data and methods used to derive these predictions are provided by Hurley and Maclaren.[16] In brief, the results are based on virtually the same set of data used by Hurley and Jacobsen[15] and also described elsewhere,[13,14] but they included coal rank (percent carbon) as a predictor variable and used a refined method to extrapolate for lifetime risk. Results were obtained from observation of 52 264 approximate 5-year man-intervals of risk for 30 500 miners having reliable dust exposure records and x-ray readings over the period of 1953 to 1977.

Each man-interval of risk gave rise to four responses based on radiographic status at the end of the interval (category 1, 2, or 3, and PMF, category 0 being obtained by subtraction). These responses were modeled using logistic methods against initial category, age, dust exposure up to the initial survey, and coal rank (percent carbon). Support for the inclusion of this variable as well as the others can be found in earlier analyses of these data.[13] Predicted probabilities of x-ray change for 5-year age groups based on these models were then obtained by substituting various levels of dust exposure and percent carbon. (For example, 83% is an average value for the common US type "A" high volatile bituminous coal.) These 5-year probabilities could then be compounded into predictions for various ages up to age 58, assuming that every miner started in category 0 at age 18 (see Hurley and Maclaren[16] for the exact details). The effect of secondary preventive measures was allowed for by assuming that all those who were found to have category 1/0 or greater immediately worked from then on in a 1 mg/m^3 environment, as allowed for by the 1969 act.

Predictions of PMF and simple CWP levels for US miners obtained using these methods for a dust concentration of 2 mg/m^3 with 83% carbon are shown in Table 1 by age and category of CWP. They indicate that 0.7% of miners who worked their full working lives in coal mining at the present maximum of 2 mg/m^3 dust (1 mg/m^3 after contracting CWP) would have PMF at age 58, while close to 2.4% would have category 2 or higher (including PMF). Figure 3 shows two curves, one for PMF and one indicating the percentage of miners predicted to have category 2 or greater simple CWP at age 58 after 40 years of mining at dust levels ranging from 1 to 8 mg/m^3 at 83% carbon. (I computed the predicted values in Table 1 and Figure 3 from the results of Hurley and Maclaren, because they presented predictions only for 2 mg/m^3.)

The above predictions apply only to type "A" high volatile bituminous coal, a type of coal that is mined generally west of the eastern divide of the United States. They do not apply to the anthracite region in eastern Pennsylvania and to certain other areas, such as central Pennsylvania and counties in the southeast of West Virginia, where low volatile bituminous coal is mined. In both of those regions, the coal rank is higher, attaining levels of 89% or greater; and the risk of PMF according to the model is correspondingly higher, being estimated at about 1.8% for miners with 40 years of tenure at 2 mg/m^3 dust in

low volatile coals. The risk of category 2 or greater is estimated to be close to 5% in such miners. The predicted risks for anthracite workers are higher still.

Differences between Predictions

The predictions for category 2 or greater simple CWP that were derived from the various exposure-response curves show broad agreement. For 35 years' exposure, the predictions range from 0% for the ISS analysis to between 1.24% and 1.61% for the results derived by Hurley and Maclaren[16] and summarized in Table 1 (interpolated at age 53 for this comparison), depending on whether PMF is included (the ISS analysis did not take PMF into account). For the two studies involving PMF, the agreement is closer, the estimated prevalences at 2 mg/m^3 being about 1%, from Hurley and Jacobsen,[15] and 0.7% from Hurley and Maclaren.[16]

The differences seen between the curves from the various studies could have been due to a multitude of factors apart from random variation. These factors include the nature of the study group (longitudinal/cross-sectional), the period of study, the presence of miner selection effects, the type of x-ray reading performed, the x-ray readers, the x-ray classification used, and the methods of model fitting and extrapolation. Considering the potential for variation, the agreement between the various studies is noteworthy.

Each study has its stronger and weaker features in relation to the others. For instance, the latest analysis, by Hurley and Maclaren,[16] is based on the study of a very large group of coal miners for whom health-related selection effects were probably small. However, the very size of the group precluded the rereading of the films using a tightly controlled protocol. For the ISS group, the opposite was true: the miners were probably fairly highly selected, having to be predominantly face workers over a 10-year period to be included in the study, but the quality of the x-ray readings was high because the x-rays were all specially reread by eight readers.

Results from successive British analyses have suggested an increasing risk of CWP over that which seemed apparent when the 1969 federal law was enacted. Among the many possible factors that could be responsible for this increase, two are discussed further. The first involves the choice of models. This applies to the ISS analysis compared with the later studies. That initial investigation used a form of model that permitted the estimation of a threshold. In contrast, all later analyses have assumed a continuum of response down to zero dust exposure.

TABLE 1—Predicted Percentages of Miners with CWP by Age

CWP Category	Age at Start of 5-Year Interval							
	23	28	33	38	43	48	53	58
0	99.96	99.71	99.15	98.27	97.05	95.46	93.49	91.15
1	0.04	0.27	0.75	1.46	2.40	3.55	4.89	6.41
2	0.00	0.02	0.09	0.22	0.45	0.76	1.15	1.60
3	0.00	0.00	0.00	0.01	0.02	0.05	0.09	0.14
PMF	0.00	0.00	0.01	0.03	0.08	0.18	0.37	0.70

Note. These predictions assume miner starts work at 18, works continually in a 2 mg/m^3 environment, obtains an x-ray every 5 years, and transfers to a low-dust (1 mg/m^3) job immediately after category 1/0 or greater is seen. Predictions are derived from results of Hurley and MacLaren.[16]

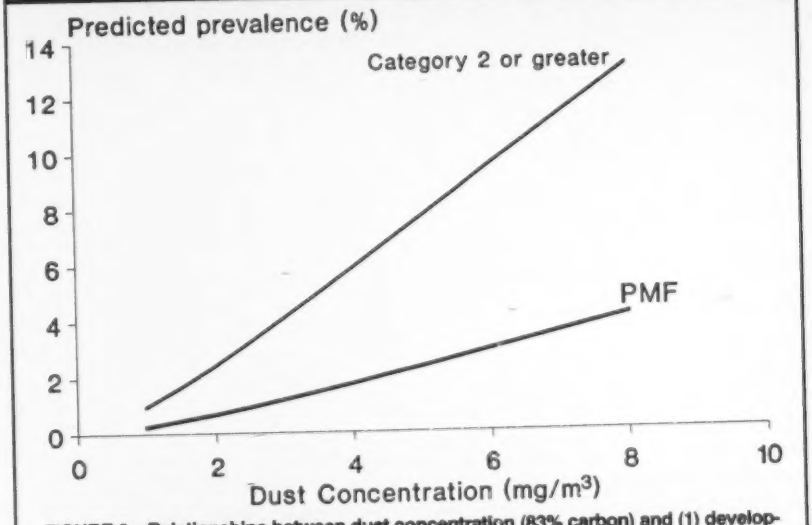

FIGURE 3—Relationships between dust concentration (83% carbon) and (1) development of category 2 or greater simple coal workers' pneumoconiosis, and (2) progressive massive fibrosis over 40 years (derived by using results given in Hurley and Maclaren[16]).

The second factor, which relates only to PMF, lies in the incorporation of information in the later studies that was ignored in the setting of the federal level: that is, incidence of PMF from simple CWP categories 0 and 1. In an early influential study of PMF incidence,[7] the risk of PMF from categories 0 and 1 appeared low compared with the obviously greater risk from the higher categories of simple CWP. For this reason, emphasis on prevention of category 2 became the major focus of the strategy for prevention of PMF. However, results from later studies of PMF incidence show a much lower gradient in risk across the categories of simple CWP, with increased risks for categories 0 and 1, and smaller risks for categories 2 and 3.[11–13] Furthermore, as exemplified in the findings of Shennan et al.,[12] the fact that most miners have category 0 or 1 simple CWP implies that a substantial fraction of the total number of PMF cases would arise from those categories, even though the risk for an individual miner might be small in that area. The later exposure-response studies with PMF as a response variable took into account this route of contracting PMF and, as a consequence, imply a higher overall risk.

Random variation obviously played a role in causing differences between the results from the various studies. However, only one of the studies provides estimates of uncertainty in the predictions. This was the ISS analysis, for which approximate confidence bounds for the 35-year predictions of risk were given. These actually indicate a range quite similar to that seen between the various PFR studies noted above.

Although the methods and models used in the PFR analysis have varied, the initial and latest studies used similar approaches to estimate the risks of CWP over a working life. In the recent Hurley and Maclaren analysis,[16] 5-year incidence and progression data were compounded into 40-year predictions. This technique is very similar to that used in the ISS, in which 10-year probabilities were compounded into 35-year estimated risks. Evidence that the ISS approach was reasonable was seen in the analysis of Hurley et al.,[17] which derived 35-year estimates of incidence directly without compounding and obtained very similar predictions to those of the ISS study (Figure 2). Hurley and Maclaren[16] expressed preference for the compounding method, since it employs the most important factor (initial category) for prediction of category 5 years later. They considered that the predictions derived using the compounding method[16] were more reliable than earlier results obtained using other methods.[15]

Application of British Results to US Mines and Miners

The validity of extrapolating results from previous studies of British mines and miners to the US situation is not known. Moreover, it may never be possible to determine exactly how valid the British findings are for the United States, given that such an evaluation would require knowledge that is now unavailable (such as that on particle-size distributions or composition for mines that are now closed). However, the following text discusses some of the more important aspects that should be considered.

Environmental factors of relevance encompass the nature of the coal mined and its surrounding or intermixed rock, coal mining practices, and other mine-specific variables. Hurley and colleagues have cautioned against indiscriminate use of their results in this respect: "There are several reasons, however, why the estimates might be inexact or misleading when applied to other conditions. . . . It is clear that at some collieries risks are far lower, or far higher, than the average values. This implies that our probability estimates will not necessarily reflect the risks to coal miners generally (in Britain or elsewhere) unless the dust concentrations and sources of unexplained colliery variability occur in a pattern broadly similar to that observed in this study."[17]

There are, however, several points of similarity between British and US mining conditions. The rank of coal mined in the two countries appears to vary over a similar range, from anthracite to high volatile bituminous.[18,19] Moreover, the average level of quartz in US mines currently also appears to be similar to that seen in British mines. Data from a recent analysis of quartz in US mines suggest that the overall mean quartz level is around 5%.[20] This compares with a mean mine average of about 4% reported for the PFR mines,[18] although this comparison does not take into account differences in the methodology used to estimate quartz levels.

Although the coals may be similar in general, there are some important differences in mining methods. Coal has been mined for many years in Britain using the longwall extraction system, a method that is relatively new to the United States. Mine operators in this country have relied on continuous miners and other coal-getting methods. Because the various methods may give rise to different particle-size distributions and involve cutting into roof, floor, or dirt band rock to differing degrees, the resulting dust clouds may vary considerably in type and composition and thus may have differing fibrogenic potential.

Another factor that needs to be considered relates to dust level estimation methods and procedures. Currently, these are different in the United States compared with those used in the British exposure-response studies. The latter involved the collection of dust concentration information, first using the thermal precipitator and then using gravimetric methods based on an instrument with a horizontal elutriator (the British Mining Research Establishment [MRE] dust sampler).[21] Later, the thermal precipitator data were converted into gravimetric equivalents using the results of comparative side-by-side sampling exercises. Furthermore, the British data were gathered according to a strategy designed specifically for epidemiological research. US procedures, in contrast, are somewhat different, being designed to assess compliance with the dust standards. Moreover, the samples are obtained using a cyclone instrument, the results of which are multiplied by a factor of 1.38 to make them equivalent to dust concentrations obtained using the MRE sampler. The uncertainties inherent in these different methods and procedures need to be considered when interpolating British exposure-response curves for application to the US coal mining situation.

Certain factors related to x-ray reading also need to be considered. First, there is evidence that US readers have tended to report more abnormality than their British colleagues in the past.[22] If this tendency still exists, prevalences of CWP estimated for US coal miners based on x-ray interpretations by US readers will be greater than those expected from the British exposure-response curves. Second, the results from the British studies summarized here were based on x-ray readings from international classification standards for pneumoconiosis that are no longer current. Because the classification is revised periodically with the introduction of different reference films, this change could easily affect the amount of abnormality reported in the future. Third, it must be noted that virtually all the PFR analyses have concentrated on small rounded opacities, whereas general US practice is to refer to combined opacity scores (rounded plus irregular opacity profusions). Moreover, the latest international classification[23] does not permit the independent assessment of rounded opacities in the same manner as past classifications. These factors imply that care will have to be taken in comparing future observed prevalences for US miners with predicted levels derived from studies using British readers and based on differing x-ray classification schemes and reference films.

Because conditions other than CWP can lead to the presence of x-ray markings that mimic simple CWP, it might be expected that a non-zero prevalence of abnormality would be seen in any cohort of subjects, including nonexposed workers. Moreover, this baseline prevalence would increase with age. Even though age is included in some of the British analyses, the form of the model forces the predictions to zero at zero dust. Hence, to date, this phenomenon has not been fully explored or incorporated into any existing analyses.

By law, current dust exposures for US underground coal miners must be less than 2 mg/m^3. This range of dust levels is actually at the extreme lower end of the range studied in the ISS analysis and other PFR analyses. Moreover, no systematic exploration of the form of the exposure-response curve in this region of dust exposure has been undertaken; hence, the proper form of this curve has not been established exactly. In particular, the existence of a threshold level of dust exposure below which no disease will occur cannot be ruled out.

As noted earlier, only the ISS analysis permitted a threshold to be estimated. There, an arc-sine transformation was fitted to the proportion of miners with cat-

egory 2 or greater simple CWP. This form of exposure-response curve is sigmoid shaped and resembles the probit and logistic transforms. It differs from them, however, in that the curve can touch the exposure axis at any point. In fact, the curve did touch the axis at dust concentration close to 2 mg/m^3, which may indicate that a threshold exists at that point. However, because no other form of model was fitted, it is not possible to determine whether the arc-sine curve was the most appropriate.

Although caution should be used in applying the British findings to the US situation, some evidence exists supporting their use. In 1984, results of a 9-year study of incidence of CWP in US coal miners were published.[24] These showed that the amount of incidence and progression of the disease was consistent with predicted levels from the initial British investigation,[9] given dust exposures mandated by federal law over the study period. These findings were supported by a study of new miners over a similar period.[25] However, these two studies covered too short a period for reliable long-term indications; further study is planned and in progress.

Evidence of a continuing trend toward lower prevalences of CWP in US miners has been reported recently.[2,3] Will the current federal disease prevention measures ensure that this trend continues until CWP is eventually eliminated from the industry? Evidence from the British studies suggests not, although the uncertainties inherent in extrapolation make it difficult to be sure as to the exact level and severity of disease to be expected. It should also be borne in mind that many miners do not transfer to a low-dust job after having an x-ray positive for CWP,[26] and that overexposure may be occurring.[27] Both phenomena suggest that observed levels of CWP incidence will be higher than those predicted. Finally, it should be noted that the results presented here are restricted to CWP; the potential for nonpneumoconiotic occupational lung diseases in coal miners should not be overlooked. □

Job Strain and Prevalence of Hypertension in a Biracial Population of Urban Bus Drivers

Cheryl L. Albright, PhD, MPH, Marilyn A. Winkleby, PhD, MPH, David R. Ragland, PhD, June Fisher, MD, and S. Leonard Syme, PhD

ABSTRACT

Objectives. In this study we tested the association between occupational stress—as measured by job demands, decision latitude, and job strain—and hypertension in a population of 1396 Black and White bus drivers.

Methods. Height, weight, blood pressure, and medical history were assessed by physical exam. Drivers completed a questionnaire assessing their work schedules, personal habits, and self-perceptions about job demands and decision-latitude.

Results. Univariate analyses revealed significant inverse associations; lower levels of job demands and job strain were associated with a higher prevalence of hypertension for Blacks and Whites. After 12 confounding variables were controlled for, the association between these two measures of occupational stress and hypertension became nonsignificant. Decision latitude was also not significantly associated with hypertension.

Conclusions. Our findings are inconsistent with previous studies' findings of a positive association between job strain and chronic diseases. The difference in results may be explained by our incorporation of individuals' perceptions in the measurement of occupational stressors and our use of individuals from a single occupation with comparable job responsibilities and income, thus controlling for potential confounding by social class. (*Am J Public Health.* 1992;82:984–989)

Introduction

Since the 1930s, social scientists have conducted research to examine how psychosocial stressors such as life events,[1,2] daily hassles,[3] behavioral characteristics,[4–6] and stressful working conditions[7–12] may be associated with the incidence and prevalence of various chronic diseases. Particular interest has been focused on the relationship between hypertension and/or coronary heart disease and occupational stressors, operationalized as specific job problems, high job demands, job dissatisfaction, and low job rewards.[13–15] This work has yielded inconsistent findings, with some studies showing positive associations[13,14,16–25] and others indicating null or negative associations.[6,12,15,26–29]

Work by Karasek and his colleagues suggests that there is a strong association between job strain, conceptualized as the joint effect of high job demands and low decision latitude or control, and an increased prevalence and/or incidence of coronary heart disease and myocardial infarction when traditional risk factors such as age, race, cholesterol, and smoking are controlled for.[14,18,20] Also, job strain has recently been shown to be positively associated with elevated diastolic blood pressure and a higher left-ventricular-mass index in a case-control study of employees from several occupations (odds ratio of 3.1).[25]

Although some studies have used case-control or prospective designs,[18,25] most of the studies using Karasek's job-strain variable have employed an ecologic study design.[14,15,20,21,30–32] In these studies an imputation method assigns job-strain scores to individuals within the same occupational census code (data obtained from large surveys such as the Health Examination Survey and the Health and Nutrition Examination Survey), then compares rates of myocardial infarction, for example, between high- and low-strain occupations.[14,20,21,30] This methodology does not permit evaluations of the associations between workers' self-perceptions of their jobs and disease status. In addition, it does not allow assessment of whether workers performing the same job duties have different perceptions of their job experience and different disease prevalence rates.

The present study was designed to test the association between self-reported job strain and clinically diagnosed hypertension within a population of bus drivers. Bus driving is an occupation characterized as having a high level of job strain as well as high rates of hypertension.[33,34]

We hypothesized that drivers who perceived their job as demanding, with little opportunity for control or decision latitude, would exhibit a higher prevalence of hypertension than would drivers who did not perceive their job in this way. In addition, we hypothesized that the association would persist after we controlled for other biobehavioral risk factors related to hypertension, such as age, race, sex, ed-

ucation, body mass index, family history of heart disease, and alcohol intake.

Methods

The present analysis was conducted as part of a larger occupational health study of urban bus drivers employed by the San Francisco Municipal Railway system. Data collection was incorporated into an existing system of medical examinations conducted as part of the drivers' required biannual license renewal process. Drivers who were examined from December 1983 to September 1985 were eligible for recruitment into the study.

Study Population

The target population consisted of 1845 San Francisco bus drivers, all of whom completed a medical examination (28 with nonstandardized blood pressure data were excluded). Seventy-seven percent completed the optional occupational psychosocial questionnaire, yielding a final study population of 1396 drivers for whom both the medical examination and optional questionnaire data were complete. A previous comparison of the drivers who completed the questionnaire with those who did not revealed no statistically significant differences between respondents and nonrespondents in prevalence of hypertension and selected demographic and behavioral characteristics.[26]

Measurement of Variables

Detailed descriptions of the data collection methods and medical procedures have been published previously.[26] Briefly, the medical examination included assessments of height, weight, blood pressure, medical history, and personal health habits. All physiological assessments were obtained in a clinic setting during normal working hours (i.e., 8 AM to 5 PM). Three standardized blood pressure measurements were taken by physicians and nurses according to the protocol defined by the Hypertension Detection and Follow-up Program.[35] All readings were obtained from the right arm with standard mercury manometers while the participants were seated. Drivers were classified as hypertensive if (1) the mean of their second and third systolic readings was equal to or greater than 140 mm Hg, (2) the mean of the second and third diastolic readings was equal or greater than 90 mm Hg, or (3) they were currently using antihypertensive medication.

After the medical examination, drivers completed a questionnaire assessing their work schedules, personal habits (health and job-related), self-perceptions about specific job problems,[26] and the 37-item job-content instrument developed by Karasek.[36,37] The present analysis focused on the three composite scales assessing psychological job demands, decision latitude, and job strain, the latter being a composite scale that represents the interaction between demands and decision latitude.[14,18,30] For each question in the scales, respondents rated (on a scale of one to four) the degree to which they agreed or disagreed with statements describing their job or job environment. A high score represents a high level of perceived job demands and/or a high level of perceived decision latitude over the job.

Measurement of Covariables

Biobehavioral factors potentially related to hypertension and assessed as confounding factors included the following: (1) age, (2) martial status, (3) education, (4) income, (5) number of years employed as a bus driver, (6) race, (7) body mass index, (8) family history of heart disease, (9) smoking (pack years), (10) fitness, (11) alcohol consumption in a week, and (12) caffeine intake per day (see Appendix A for definitions of covariables).

Statistical Analyses

Logistic analyses were conducted with hypertension status as the outcome variable. Univariate analyses were performed initially, followed by multivariate logistic analyses that included job demands and decision latitude as the main effects, the job strain variable as the interaction term, and the potential 12 confounding factors. Job demands and decision latitude were tested separately as continuous variables and as dichotomous "median split" variables with high job demand > 31.5 and low decision latitude ≤ 30.9. These two categorical variables were used to create the four-level rank-ordered job-strain variable that corresponded to Karasek's 2×2 model of job strain, with low job demand and low decision latitude representing the passive job category; low job demand and high decision latitude representing the low-strain category; high job demand and high decision latitude representing the active category; and high job demand and low decision latitude representing the high-strain category. The latter category was hypothesized to carry the greatest risk.[14,20,25]

Results

The sample was predominantly male (91%) and was 60% Black, 17% White, 13% Asian, and 8% Hispanic. The drivers' ages ranged from 20 to 65 years; the mean age was 42. The majority (63%) had been employed by the San Francisco bus company for 9 years or longer.

The mean and standard deviation was 32.0 ± 6.04 (range, 12 to 48) for the job demands scale and 30.8 ± 5.00 (range, 14 to 45) for the decision latitude scale. The mean value for job demands is similar to those reported previously, but the mean value for decision latitude is somewhat lower[15,25,37] (see Appendix B).

Table 1 presents the descriptive statistics for the drivers according to job strain category. The active job strain category contained the lowest proportion of hypertensives. Chi-square analyses were significant for these descriptive variables; higher percentages of younger drivers, women, and drivers with less than 10 years of employment fell into the active and high-strain categories. (When we examined social-class variables, our correlational analyses revealed a positive association between income and hypertension [$r = .07$, $P < .02$], but a negative association between education and hypertension [$r = -.060$, $P < .02$].)

Table 2 shows the percentage of hypertensives within each quintile of job demands and decision latitude. According to our hypothesis, hypertension rates should be higher within the higher levels of job demands and lower within the higher levels of decision latitude. Although not statistically significant, the trend for decision latitude was in the hypothesized direction. Job demands yielded a significant chi-square with a P value of less than .01; however, the trend was the opposite of the hypothesized relationship. Analyses by race revealed similar trends in prevalence of hypertension across the job-demands quintiles for Black and White drivers (sample sizes for Asian and Hispanics drivers were insufficient for analyses).

Because drivers with more seniority are allowed to select their bus routes (i.e., they have more latitude to select less demanding routes), it is possible that older drivers with more hypertension might perceive fewer job demands. This possibility is supported by the data reported in Table 1. Of those drivers in the passive category, 24% were older than 50, whereas of those in the active or high-strain category, only 12% were older than

TABLE 1—Characteristics of Respondents by Job-Strain Category (%)

[b] $\chi^2 = 2.7$ (df = 4), $P = .61$.

50. Thus, a multivariate logistic analysis was needed to investigate this association both by controlling for age and length of employment and to test any interaction between job strain and length of employment.

As shown in Table 3, univariate analyses revealed significant inverse associations between the prevalence of hypertension and job demands and job strain (odds ratios of .84 and .88, respectively). The univariate test for decision latitude was in the hypothesized inverse direction but was not statistically significant. Multivariate logistic regression analyses in which age, years of employment, body mass index, and nine other factors were controlled for revealed no significant associations between any of the three occupational stressors and the prevalence of hypertension. Similar results were found for both the continuous and dichotomous quantifications of the three variables.

To examine whether an interaction existed between perceived job strain and covariables such as age, sex, and race, we assessed evidence of a first-order multiplicative interaction, using unconditional maximum-likelihood estimation methods.[38] Product interaction terms (between each of the covariables and job strain) were added to the multivariate model and the model was compared with a reduced model without interaction terms. A chi-square statistic, used to test the difference between the two models' log likelihood ratios, revealed no significant interaction between the job stress variables and any of the covariables.

Separate multiple regression analyses examining the impact of the three occupational stress indices on mean systolic and mean diastolic blood pressures within the subsample of normotensives (systolic blood pressure < 140 and diastolic blood pressure < 90) were also not statistically significant.

Discussion

We found univariate inverse relationships between job demands, job strain, and the prevalence of hypertension in a biracial blue-collar population of urban bus drivers. These negative associations were opposite to our a priori hypothesis of a positive relationship between these variables. The univariate inverse associations were not, however, supported by the multivariate logistic analysis that adjusted for 12 covariables. Thus, in the present study we found no association between subjective reports of occupational stress and prevalence of hypertension.

Previous studies using subjective self-reported measures of occupational stress have yielded inconsistent results. Some have yielded positive associations with diastolic or systolic blood pressure,[13,16,22,25] whereas others have found no associations with elevated blood pressure or hypertension.[6,12,29,32] These inconsistencies in the literature could be related to differences in populations, study design, job stress instruments, and/or outcome measures. However, the similarities between our study and the recent case-control investigation of job strain, diastolic blood pressure, and left-ventricular-mass index conducted by Schnall et al.[25] warrants discussion. Both studies used the same instruments to assess job strain and similar statistical analyses. Schnall et al. found that individuals from different occupations with high-strain jobs had an increased likelihood of having elevated diastolic blood pressure, whereas our analyses revealed that, within one occupation, there was no significant association between job strain and prevalence of hypertension or systolic/diastolic blood pressure. Although there were methodological differences between these two studies (e.g., selection of subjects and blood pressure measures), two major differences between our study and that of Schnall et al. require elaboration. Our study population was largely Black (60%), whereas that of Schnall et al. was largely White (80%). Schnall and colleagues examined job strain across a variety of occupations, whereas our study included only bus drivers. Previous analyses of bus drivers' work have shown that drivers are exposed to a wide range of psychological as well as physical stressors,[33] and comparisons across occupations have shown bus drivers to have higher rates of hypertension and other diseases than do workers in other blue-collar occupations.[33,34]

One explanation for the divergent findings of these two studies is that our study population, which was from one occupational group, could have exhibited insufficient variability in the assessments of job strain. We found, however, that the mean value for job demands for our study population was quite similar to that reported by Reed et al. and Karasek et al. in cross-occupational studies[15,37] and by Schnall et al. in their recent case-control study[25] (the mean value for decision latitude was somewhat lower in the present study; see Appendix B). Although our standard deviation for decision latitude was considerably lower than those reported by Karasek et al.,[37] it was similar to those reported by Reed et al.[15] and Schnall et al.[25]; thus, the within-occupation variability of self-reported job stress in the present study is similar to the between-occupation variability found in the latter two studies. This similarity indicates that individuals working in jobs with similar duties can have different perceptions of their duties and can cope with them with varying degrees of success. And although the duties may be similar, there may be many factors that vary between workers (e.g., for bus drivers, the number of passengers or the traffic volume on different bus routes). Thus there does not appear to be bias from limited variability in our measure of occupational stress.

Another reason for the inconsistency between the present study and Karasek's earlier studies may be the different socioeconomic status (SES) of the respondents. In the analyses of Karasek and his coworkers, education is often used as a covariable[14,18,20,25,32]; however, factors other than education that are related to SES (e.g., income, job status) may confound the association between occupational stress and chronic disease. For example, Marmot and his coworkers found that low SES, as measured by grade of employment, was associated with increased mean blood pressure, prevalence of hypertension, and stroke mortality.[39,40] Several similar investigations in which occupation has been used as an indicator of SES have found that blood pressure rises as SES decreases.[41,42] In contrast to the work of Karasek and his colleagues, the present study involved a population that was similar in socioeconomic status, and individual differences in education and income were controlled for in the analysis. This method of controlling for SES in both the design and analytic phases of the study may explain some of the disparities in results.

TABLE 3—Logistic Analyses of Hypertension and Occupational Stressors

	Regression Coefficient	Odds Ratio (95% CI)	*P* Value
Univariate analyses			
Job demands	−.028	0.84 (.75, .94)	<.01
Decision latitude	−.018	0.91 (.82, 1.02)	.12
Job strain[a]	−.119	0.88 (.78, .98)	.03
Multivariate analyses[b]			
Job demands	−.008	0.95 (.84, 1.03)	.46
Decision latitude	−.017	0.92 (.81, 1.04)	.19
Job strain[a]	−.011	0.98 (.86, 1.13)	.85

[a]Job strain was measured by a four-level rank-ordered combination of job demands and decision latitude.
[b]Multivariate analyses tested the association between occupational stressors and prevalence of hypertension with adjustment for age, race, sex, education, income, marital status, years employed, body mass index, smoking, caffeine, alcohol, and fitness.

Differences between the present study and previous studies are unlikely to be due to inadequate sample size. Of the 1407 subjects in our sample, 448 were classified as hypertensive. This number is more than the total sample size used in two similar studies of occupational stress and diastolic blood pressure (n = 288 and n = 215).[13,25] Thus, compared with two studies that found a positive association between occupational stress and diastolic blood pressure, our study had almost six times as many subjects and five times as many hypertensives.

Inconsistencies could have, however, occurred because of selection or measurement bias. Selection bias could have occurred if the subjects in the present study were atypical with regard to their perceptions about their job or their risk factors for hypertension, or if those hypertensives with the highest level of job stress were more likely to terminate employment. As discussed above, the mean values for the occupational stress variables were quite similar to those reported in previous studies; thus the drivers' job scores were not unusual. Furthermore, our study population and that used by Schnall et al. were extremely similar in terms of risk factors for hypertension, such as age, body mass index, prevalence of smokers, and systolic and diastolic blood pressures. Finally, in a previous study of the same sample in which drivers were asked to rate specific job stressors, we found no significant differences between the job-stress scores of hypertensives who left the job and the scores of those who remained.[26] Although measurement bias is possible, it was minimized by (1) distinct separation, both in time and in setting, of blood pressure measures and driver's ratings of job strain; (2) fidelity to the Karasek instrument; and (3) strict adherence to standardized protocols for measuring blood pressure.

Therefore, these potential biases do not appear to account for our negative findings. Bus drivers' self-perceptions about the level of job demand and decision latitude involved in their job does not appear to be associated with hypertension or high blood pressure. In fact, there may even be an inverse association between job stress and hypertension. Significant inverse relationships between subjectively assessed job stressors and hypertension or blood pressure were recently found in two studies.[26,32] In the first study,[26] Winkleby et al. found an inverse association between specific work-related stressors (e.g., accidents, traffic, and tight schedules) and hypertension (odds ratio = 0.84; CI = 0.75, 0.99; $P < .04$), using the same sample of bus drivers as the current study. In the second study an inverse association between job demands and systolic blood pressure (regression coefficient = −.79; $P < .05$) was found in one of the five databases reviewed in a meta-analysis by Pieper et al.[32] These studies suggest that low levels of job strain may be associated with higher hypertension or that hypertensives may suppress their feelings toward job stressors by underreporting the frequency of specific stressful situations and the levels of emotional reactivity associated with these events.[26]

Summary and Implications

In summary, we studied workers with comparable job responsibilities and similar income levels in an objectively defined high-stress occupation and found no significant association between hypertension and job demands, decision latitude,

or job strain. This lack of association is in contrast to the findings of Karasek et al., who examined workers from a wide range of social classes. If the studies of Karasek et al. did not adequately control for SES, then it may *not* be high demand/low decision latitude that is associated with high coronary heart disease morbidity or mortality, but the low SES that accompanies occupations with such stressors. We hypothesize that social class could confound the association between occupational stress and chronic disease, or that SES and occupation may be so highly correlated that it is difficult to separate their independent effects. Therefore, until the effects of SES can be distinguished more precisely from occupation-based indicators of job stress, ecologic investigations of different occupations should be interpreted cautiously.

Our results raise questions about the relationship between Karasek and his colleagues' operationalization of occupational stress and the prevalence of hypertension. In addition, the interrelationships between coping strategies (denial and repression), occupational stress, social class, and chronic disease remain unclear. Future investigations should rigorously evaluate coping styles, how they interact with occupational stressors, and whether they precede or follow the development of hypertension.

To fully address the inconsistencies evidenced in this study, future studies should use prospective designs that assess objective as well as subjective measures of occupational stress; evaluate coping styles (especially repressive coping styles); control for the various dimensions of social class; and follow workers for the development of multiple chronic diseases such as hypertension, coronary heart disease, and stroke. Obviously this type of study would be expensive and difficult to implement, but smaller studies investigating how hypertensives explicitly deal with various occupational stressors, measured both subjectively and objectively, may provide insights into the inverse and null associations found between occupational stressors and hypertension. □

APPENDIX A—Definitions of Covariables

Marital Status = married, separated, divorced, widowed, and single/never married.
Education = less than 11th grade, high school graduate, technical school/some college, college graduate or higher.
Income = rank-ordered into four categories, less than $25,000 to $35,000 or more.
Race = Black, White, Asian, Hispanic, and other.
Body Mass Index = Weight in kilograms, divided by height in meters squared.
Family History of Heart Disease = positive if participant's mother, father, or siblings ever had high blood pressure, heart disease, stroke, or a cardiovascular disease-related death.
Fitness = hours per week of moderately hard physical activity.
Alcohol Consumption = total drinks of wine, beer, or hard liquor in an average week.
Caffeine Intake = total cups of coffee or soft drinks per day.

Call for Abstracts for Epidemiology Late-Breaker Sessions

Exchange Session

The Epidemiology Section will sponsor a "late-breaker" Epidemiology exchange on Wednesday, November 11, 1992, during APHA's 1992 annual meeting in Washington, DC. The exchange will provide a forum for presentation of investigations or methods that have been conceived, conducted, and/or concluded so recently that members could not meet the deadline for abstract submission to other Epidemiology sessions. Abstracts should report on work conducted during the last 6–12 months.

Abstracts of fewer than 200 words (any format) and a stamped, self-addressed return envelope should be submitted to Polly A. Marchbanks, PhD, Chief, EIS Program, Epidemiology Program Office, Mailstop C08, Centers for Disease Control, Atlanta, GA 30333; (404) 639-3588.

Abstracts must be *received* by September 28, 1992. Decisions will be made by October 5, 1992.

Poster Session

The Epidemiology Section will again be sponsoring a late-breaker poster session at the annual meeting. The session will take place on Wednesday, November 11, 1992. Work completed in 1992 is eligible for consideration. Submit an abstract of fewer than 200 words (any format) and a *return envelope* to Cathey Falvo, MD, MPH, Graduate School of Health Science, Munger Pavilion, New York Medical College, Valhalla, NY 10595; tel. (914) 993-4323.

Abstracts must be *received* by October 2, 1992. Decisions will be mailed October 5, 1992. Students and recent graduates are particularly encouraged to submit abstracts.

Use of Hair Coloring Products and the Risk of Lymphoma, Multiple Myeloma, and Chronic Lymphocytic Leukemia

Shelia Hoar Zahm, ScD, Dennis D. Weisenburger, MD, Paula A. Babbitt, Robert C. Saal, Jimmie B. Vaught, PhD, and Aaron Blair, PhD

ABSTRACT

Objectives. Hair coloring products are widely used and contain components that are mutagenic and carcinogenic. An association between occupational exposure to hair coloring products and hematopoietic cancers has been reported, but the risk for these cancers among users has not been carefully evaluated.

Methods. We conducted a population-based, case-control study with telephone interviews from 385 non-Hodgkin's lymphoma cases, 70 Hodgkin's disease cases, 72 multiple myeloma cases, 56 chronic lymphocytic leukemia cases, and 1432 controls.

Results. Among women, use was associated with odds ratios of 1.5 for non-Hodgkin's lymphoma, 1.7 for Hodgkin's disease, 1.8 for multiple myeloma, and 1.0 for chronic lymphocytic leukemia. Risk was higher for permanent hair coloring products than for semi- or nonpermanent products, particularly for dark colors. Long duration and early age of first use tended to increase risk, but the patterns were inconsistent. Use was much less common in men and did not significantly increase risk.

Conclusions. The use of hair coloring products appears to increase the risk of non-Hodgkin's lymphoma. Multiple myeloma and Hodgkin's disease were also associated, although based on far fewer subjects. If these results represent a causal association, use of hair coloring products would account for 35% of non-Hodgkin's lymphoma cases in exposed women and 20% in all women. (*Am J Public Health.* 1992; 82:990–997)

Introduction

Hair coloring products are widely used and are known to contain components that are mutagenic and carcinogenic in animals.[1–4] Associations between occupational exposure to hair coloring products and hematopoietic cancer have been reported,[5–9] but little is known about the risks for hematopoietic cancers among users of such products. Two case-control studies have suggested that use of hair coloring products may increase the risk of leukemia and non-Hodgkin's lymphoma.[10,11] We evaluated risks associated with the use of hair coloring products in a population-based, case-control study of incident lymphoma, multiple myeloma, and chronic lymphocytic leukemia conducted in eastern Nebraska. Our report includes both sexes and involves more detailed data on personal use of hair coloring products than earlier studies.

Methods

Cases of non-Hodgkin's lymphoma, Hodgkin's disease, multiple myeloma, and chronic lymphocytic leukemia among White men and women, aged 21 years or older, residing in the 66 counties of eastern Nebraska, and diagnosed between July 1, 1983, and June 30, 1986, were identified through the Nebraska Lymphoma Study Group and area hospitals. Details concerning completeness of reporting and other study methods have been published elsewhere.[12] There were 426 non-Hodgkin's lymphoma, 73 Hodgkin's disease, 82 multiple myeloma, and 69 chronic lymphocytic leukemia cases histologically confirmed. Non-Hodgkin's lymphoma cases were reviewed and classified according to the Working Formulation[13] and underwent immunologic typing.[14,15] The various histologic types of non-Hodgkin's lymphoma were grouped as follicular (29%), diffuse (68%), or not otherwise specified (3%). The cases were also categorized histologically into follicular center cell (Working Formulation categories B through G and J: 71%) and nonfollicular center cell (categories A, H, I, and K: 29%) groups.[16] Composite lymphomas with follicular and diffuse components of the same cell type were assigned to the follicular category. Composite lymphomas with different cell types were assigned to the more indolent cell type. B-cell lymphomas accounted for 81% of the non-Hodgkin's lymphoma cases, whereas 8% of the cases were T-cell lymphomas. The remaining cases could not be classified: 5% were of indeterminant immunologic type and 5% had no specimens available for study.

The controls were selected from residents of the same 66-county area by 3:1 frequency matching by race, sex, vital status, and age (± 2 years) to the combined age distribution of the four cancer case series (non-Hodgkin's lymphoma, Hodg-

Shelia Hoar Zahm and Aaron Blair are with the Occupational Studies Section, National Cancer Institute, Rockville, Md. Dennis D. Weisenburger is with the Department of Pathology and Microbiology and the Eppley Institute for Research in Cancer and Allied Diseases, and Paula A. Babbitt was with the Department of Pathology and Microbiology, University of Nebraska Medical Center, Omaha. Robert C. Saal and Jimmie B. Vaught are with Westat Inc, Rockville, Md.

[a]Age adjusted.
[b]Subjects could have used more than one type of hair coloring product and therefore may contribute to more than one category.

kin's disease, multiple myeloma, and chronic lymphocytic leukemia). For living cases under age 65, 472 controls were selected by two-stage random-digit dialing.[17] For living cases aged 65 or older, 603 controls were selected from Health Care Financing Administration (Medicare) records. For deceased cases, 580 controls were selected from the Nebraska state mortality files using the additional matching factor of year of death. Persons with an underlying cause of death of non-Hodgkin's lymphoma, Hodgkin's disease, multiple myeloma, leukemia, malignancy of unknown site, aplastic anemia, suicide, homicide, or legal intervention were excluded as controls. A total of 1655 controls was selected.

Telephone interviews were conducted with 385 (201 men, 184 women) non-Hodgkin's lymphoma cases, 70 (35 men, 35 women) Hodgkin's disease cases, 72 (32 men, 40 women) multiple myeloma cases, 56 (37 men, 19 women) chronic lymphocytic leukemia cases, and 1432 (725 men, 707 women) controls, or their next of kin. The interview response rates were 90%, 96%, 88%, 81%, and 87%, respectively. The overall control response rate was 84% (a weighted average accounting for the 91% response rate in the household census phase of the random-digit dialing procedure, the 94% response rate of the randomly selected eligible random-digit dialing controls, the 84% response rate of the Health Care Financing Administration controls, and the 83% response rate of next of kin of deceased controls).

The interview questions included the ages of first and last use of products that gradually change hair color, of nonpermanent or semipermanent hair coloring products (defined as products that rinse out after a few shampoos), and of permanent hair coloring products (defined as products that last until the hair grows out). Users of non- or semipermanent products and permanent products were also asked the usual frequency of use and the basic color used most often. Because being diagnosed with cancer could affect use of hair coloring products, exposure histories for all cases and controls were truncated as of December 31, 1982, which precedes the earliest diagnosis date for all cases. Other known and suspected risk factors for the cancers under study, such as family history of cancer and pesticide exposures, were also included in the interview.

The measure of association was the odds ratio (OR). All risk estimates were adjusted for the effects of age by stratification (21 through 39, 40 through 59, 60 through 69, 70 through 79, and greater than 79 years). Maximum likelihood estimates of the overall risk and 95% confidence intervals (CIs) were computed by Gart's method.[18] For duration–response and frequency–response relationships, significance was assessed by means of Mantel's one-tailed linear trend test.[19] Logistic regression analyses were conducted using an SAS procedure for polychotomous outcomes, a method that accounts for the use of a single control group for the four case groups in its estimation of variance.[20] Attributable risks and CIs were calculated using the method proposed by Whittemore.[21]

Results

Table 1 presents the number of cases and controls and the ORs by sex and hair coloring product type. Among women, use of any hair coloring product was associated with non-Hodgkin's lymphoma, Hodgkin's disease, and multiple myeloma. Non-Hodgkin's lymphoma was significantly associated with the use of both semi- and nonpermanent hair coloring products (OR = 1.4) and permanent

[a]Age adjusted.
[b]Subjects could have used semi- or nonpermanent and permanent hair coloring products, and, therefore, may appear in the table twice.

hair coloring products (OR = 1.7). Women who used permanent hair coloring products only had an OR for non-Hodgkin's lymphoma of 1.9 (95% CI = 1.1, 3.4). Hodgkin's disease and multiple myeloma showed significant associations with the use of permanent hair coloring products. Women who had used permanent hair coloring products only had an OR of 3.4 (95% CI = 1.1, 10.7) for Hodgkin's disease, while users of semi- or nonpermanent products had an OR of 0.8. Chronic lymphocytic leukemia was not associated with the use of any hair coloring products. For all cancer types among women, except chronic lymphocytic leukemia, the risks associated with permanent hair coloring products were higher than those for semi- or nonpermanent hair coloring products, although CIs overlap.

Among men, the ORs for hair coloring product use were 0.8 for non-Hodgkin's lymphoma, 1.7 for Hodgkin's disease, 1.8 for multiple myeloma, and 1.0 for chronic lymphocytic leukemia. Non-Hodgkin's lymphoma was elevated among men who were long-term users of products that gradually changed hair color (1 year: OR = 1.0; 2 through 5 years: OR = 0.2; 6+ years: OR = 1.6; 95% CI = 0.5, 5.0), but neither their risk nor the duration trend (P = .362) was significant. The number of men using other hair coloring products was much less than the number of women and precluded meaningful analysis. The remaining results presented are for women only.

Risk varied by the most frequently used hair coloring product color (Table 2). For non-Hodgkin's lymphoma and multiple myeloma, the risks were higher among women who most often used brown or brunette, black, or red hair coloring products. In general, the risks associated with these darker color products were higher among users of permanent hair coloring products than semi- or nonpermanent products.

The risk of non-Hodgkin's lymphoma increased significantly with the duration of use and younger age at first use of semi- or nonpermanent products, although the risks dropped off in the highest category of both variables (Table 3). Risk also increased significantly with duration of use of dark permanent hair coloring products and younger age at first use of permanent hair coloring products, but did not show consistent exposure–response gradients (Table 4). Risk did not increase with frequency of use. The same patterns, with higher levels of risk, were seen when the analyses were restricted to black, brown/brunette, and red hair coloring products only. In general, users of permanent hair coloring products had a higher risk of non-Hodgkin's lymphoma relative to women who never used any hair coloring products and relative to women who used semi- or nonpermanent hair coloring products at most levels of duration, age, and frequency of use. Women who began using hair coloring products prior to 1970 had slightly lower risks (semi- or nonpermanent: OR = 1.3; permanent: OR = 1.6) than women who began using hair coloring products after that date (semi- or nonpermanent: OR = 1.5; permanent: OR = 2.2).

Because many of the age and time characteristics were interrelated, we performed polychotomous logistic regression entering all the variables presented in Tables 1 through 4. The results of the regression analyses were similar to the analyses already presented. Color of hair coloring products used, duration of semi- or nonpermanent hair coloring product use, decreasing age of first use of permanent hair coloring products, and age at diagnosis significantly increased the risk of non-Hodgkin's lymphoma. The other age, duration, and frequency variables were not significantly associated with non-Hodgkin's lymphoma.

Women who had ever used semi- or nonpermanent hair coloring products had a higher risk of follicular center cell lymphoma (OR = 1.6; 95% CI = 1.0, 2.5) than those who developed nonfollicular center cell lymphoma (OR = 1.1; 95% CI = 0.6, 2.0). Users of permanent hair coloring

[a]Age adjusted.
[b]The age categories for first use of permanent hair coloring products differ from the categories used for semi- or nonpermanent hair coloring products because use patterns differ. For both analyses, the categories were selected to achieve as equal a distribution of the control subjects as possible.

products also had a higher risk of follicular center cell lymphoma (OR = 2.0; 95% CI = 1.1, 3.5) than those who developed nonfollicular center cell lymphoma (OR = 1.3; 95% CI = 0.6, 2.8). Women using dark permanent products also had the highest risk for follicular center cell lymphoma (OR = 2.5; 95% CI = 1.3, 4.9) and had an almost threefold increased risk (OR = 2.8; 95% CI = 1.2, 6.5) of developing large cell lymphoma of follicular center cell origin (categories D, G, and J).

Users of semi- or nonpermanent hair coloring products had similar risks for B-cell lymphoma (OR = 1.5; 95% CI = 1.0, 2.2) and for T-cell lymphoma (OR = 1.5; 95% CI = 0.3, 7.7), whereas users of permanent hair coloring products had a higher risk for T-cell lymphoma (OR = 3.5; 95% CI = 0.6, 19.3) than for B-cell lymphoma (OR = 1.7; 95% CI = 1.0, 2.9). However, the ORs were not significantly different from each other.

Adjustments for family history of cancer, cigarette smoking, herbicide use, and insecticide use did not change the risk estimates for non-Hodgkin's lymphoma and hair coloring product use.

Risk estimates for non-Hodgkin's lymphoma based on data from self-respondents or proxy respondents were similar for use of any hair coloring products (self: OR = 1.5; proxy: OR = 1.6), semi- or nonpermanent products (self: OR = 1.4; proxy: OR = 1.4), permanent products (self: OR = 1.7; proxy: OR = 1.9), and products that changed hair color gradually (men, self: OR = 0.8; proxy: OR = 0.9). Risks and trends associated with age at first use and duration of semi- or nonpermanent hair coloring products and age at first use of permanent products were slightly stronger among self-respondents than among subjects whose data were supplied by proxies. No meaningful differences were seen between self-respondents and proxies for frequency and color of semi- or nonpermanent hair coloring products. Conversely, risks by duration, frequency, and color of permanent hair coloring products were slightly higher among subjects whose data were supplied by proxies than among self-respondents.

There were far fewer cases of the other three cancers than of non-Hodgkin's lymphoma, which limited our ability to investigate risks by use characteristics. Nevertheless, significant trends in risk for multiple myeloma were observed for decreasing age at first use of semi- or nonpermanent hair coloring products (Table 3) and duration, decreasing age at first use, and frequency of use of permanent hair coloring products (Table 4); however, at least in part because of small numbers, most risk patterns were inconsistent. Polychotomous logistic regression analyses, based on all variables in Tables 1 through 4, revealed only color to be significantly associated with risk of multiple myeloma. Nonsignificant associations were observed with decreasing age at first use of semi- or nonpermanent-or permanent hair coloring products and frequency of use of permanent hair coloring products.

A significant trend was seen for Hodgkin's disease and decreasing age at first use of permanent hair coloring products (Table 4), but the significant trend was primarily due to the lack of Hodgkin's disease cases in the older age at first use categories. The Hodgkin's disease cases were younger on average than the controls, who were frequency matched to the combined group of four cancer types; thus, the difference observed by age at first use may not have etiologic significance. The logistic regression analyses showed age at diagnosis and decreasing age at first use of permanent hair coloring products to be significantly associated with development of Hodgkin's disease. Nonsignificant associations were seen with duration and younger age at first use of semi- or nonpermanent hair coloring products.

Discussion

Experimental studies have shown that hair coloring products contain mutagenic and carcinogenic compounds, which vary by hair coloring product type and color.[1-4] Although some of these components have been removed from use over the last two decades, many carcinogenic aromatic, nitroso, and amino compounds remain and are found in both semipermanent and permanent hair coloring products. Permanent hair coloring products also contain oxidizing agents that allow the dye to irreversibly bind to the hair shaft. This generally lowers absorption by the skin of specific aromatic amines, but the oxidation process also results in the formation of some products, such as the three-ringed "Bandrowski-base," that are absorbed.[1] Many different chemical dyes can be found in most color formulations, but they usually occur in greater concentrations in the black, brown, and red dyes than in blond and silver bleach toner formulations. It is interesting that, in the present epidemiologic study, the variation in cancer risks by product type and color is somewhat consistent with what would be expected based on the concentration of the constituents and biochemical action of the product formulations. Hair coloring products that gradually change hair color have been shown to be absorbed by the users.[22] For example, gradual products contain lead acetate[23,24] and result in absorption of lead by the users.[22] Although the target sites for carcinogenic hair coloring components in feeding studies of rats and mice have generally been the urinary tract, liver, mammary gland, skin, forestomach, and thyroid gland,[25] there have been reports of increased lymphoma in mice in two skin painting studies of hair dyes.[26,27]

In the present study, significant risks were observed for overall use of hair coloring products, darker colors, and trends of some use characteristics, but the patterns of risk by some use characteristics were inconsistent. These inconsistencies could arise because the association is noncausal, because of chance (numbers of exposed cases were small), or because of misclassification of self- and proxy-reported exposure data for some of the use characteristics. There is little information in the scientific literature on the quality of self- or proxy-reported histories of hair coloring product use. In a small reliability study of 32 women (16 cases and 16 controls), the correlation between reported duration of hair dye use from two interviews 1 year apart was .86 and was similar for cases and controls.[28] The correlation for frequency of use (.92) was slightly higher. We have no such data on our subjects, and no information on recall over longer time periods or by surrogate respondents. It seems reasonable, however, to assume that the quality of reporting on type and color of hair coloring product used would be more accurate than reporting on age of first use or annual frequency of use. Recall worsens with the degree of detail required.[29] The type of misclassification of the use characteristics likely to occur would tend to reduce ORs and dampen or disrupt trends.[30,31] In the present study, there was little difference between self-respondents and proxy respondents for risk estimates of non-Hodgkin's lymphoma for the overall "ever" use of hair coloring products. Although the number of subjects in each category was small and risk estimates were highly variable, we did examine use characteristics by respondent type. Slightly greater risks and trends were seen among self-respondents than among proxies for the age at first use of any hair coloring product and duration of semipermanent hair coloring products.

These data suggest that inclusion of proxies, with their potentially less accurate data, may have resulted in underestimates of true risks and dampened trends for the detailed use characteristics. However, proxies yielded slightly higher risk estimates for duration, frequency, and color of permanent hair coloring products than self-respondents. Similar results for subjects and proxies for semipermanent frequency variables suggest that the data from the two groups may be equally poor.

Case response bias needs to be considered as a possible explanation for the associations observed in this study. With several cancers showing an association, one cannot easily dismiss case response bias completely. Shore et al.,[28] however, found little evidence for case response bias for hair dye use in breast cancer patients in 1979. More recent data on potential for case response bias with respect to hair coloring product use are not available. Awareness of potential health risks associated with hair coloring products may have increased. It seems unlikely, however, that case response bias would operate in a manner so as to yield risks by type and color of product that are consistent with what might be expected based on the concentration of oxidizers and dyes in the formulations, facts not likely to be known by study subjects.

We were able to adjust for the influence of several known or suspected risk factors for non-Hodgkin's lymphoma and the other cancers and found no evidence of confounding. It has been hypothesized that the hair graying or other conditions that lead to the use of hair coloring products are a reflection of hormonal status or other factors that themselves are responsible for increased cancer risk.[32] While this may be relevant for breast cancer, there is no evidence that hormonal factors play a role in the development of non-Hodgkin's lymphoma,[33] Hodgkin's disease,[34] or multiple myeloma.[35] A single report links the use of hair dyes to connective tissue disorders, such as systemic lupus erythematosus and scleroderma.[36] These acquired disorders of immunity have also been associated with an increased risk of non-Hodgkin's lymphoma[33] and multiple myeloma, although the association with multiple myeloma was observed in clinical series[37] but not case-control studies.[38–40] These findings suggest that hair coloring products may act by affecting the immune system. Freni-Titulaer et al.[36] hypothesized that the association between connective tissue disease and hair coloring products may be affected by acetylator phenotype. Slow acetylators would be at greater risk than fast acetylators. The aromatic amines in hair coloring products, which are absorbed through the scalp, are metabolized through acetylation. Genetically determined metabolic phenotypes could affect risk, dampening apparent associations in populations that are heterogeneous for the metabolic phenotype.

Most epidemiologic studies of hair coloring products and hematopoietic cancers have focused on people who were occupationally exposed (i.e., cosmetologists). The relative exposure levels of professional compared with personal use are unknown. If cosmetologists use protective gloves, their dermal exposures may, in fact, be less than those of persons whose hair is being colored. Two reports of significant excesses of multiple myeloma,[7,9] one report of a significant excess of leukemia,[9] and several reports of nonsignificant excesses of all hematopoietic cancers combined[5,8,41–43] have been reported among cosmetologists.

Far fewer data are available on the risk of hematopoietic cancers among users of hair coloring products. A study of registered nurses had fewer than expected lymphoma cases (10 vs 15.7) among women who had used permanent hair dyes.[44] Another study, which combined lymphoma and leukemia, reported an excess risk in London but a deficit risk in Toronto associated with use of permanent or semipermanent dyes.[45] The study by Cantor et al.[11] of non-Hodgkin's lymphoma and leukemia is by far the largest case-control study to address the risk for these tumors in hair coloring product users. Both cancer types were associated with hair dye use, but the study was restricted to men. The present study included only 21 male cases (11 non-Hodgkin's lymphoma, 3 Hodgkin's disease, 4 multiple myeloma, and 3 chronic lymphocytic leukemia) who reported use of hair coloring products; therefore, we were unable to thoroughly evaluate their risk or the consistency of the results for men between the two studies. Our data suggest that men are more likely to use products that gradually change hair color (6% of controls) than other types of hair coloring products (1% of controls). More research is needed on the risk of these gradual hair coloring products. There were only 12 cases of chronic lymphocytic leukemia (9 women, 3 men) exposed to hair coloring products in the present study, too few to assess risk with any confidence. The study of Cantor et al.[11] found at least a twofold excess risk of leukemia associated with hair coloring product use in men for a number of different leukemia subtypes, but not chronic lymphocytic leukemia and acute nonlymphocytic leukemia. A case-control study of acute nonlymphocytic leukemia conducted in Baltimore, however, found an association with use of hair dyes among both men and women.[10] To our knowledge, there are no reports on the risk of multiple myeloma associated with the use of hair coloring products, although there are several reports of excesses of multiple myeloma in persons occupationally exposed to hair dyes.[35]

With the widespread use of hair coloring products among women (46% of the controls), the question of cancer risk is an important public health issue. Using the Whittemore method[21] for calculating attributable risks and CIs, based on a relative risk of 1.53 for non-Hodgkin's lymphoma for ever having used any hair coloring product, these exposures would account for 35% (95% CI = 9%, 52%) of the non-Hodgkin's lymphoma occurring in exposed women and 20% (95% CI = 3%, 35%) in all women. Non-Hodgkin's lymphoma is one of the most rapidly increasing cancers in developed countries,[46,47] second in the United States only to melanoma and female lung cancer.[48] Between 1973 and 1987, the incidence of non-Hodgkin's lymphoma in the United States increased by more than 50%.[48] Some, but not the majority, of this increase is due to lymphomas arising in patients with the acquired immunodeficiency syndrome. Historical data on trends in hair coloring product use, which would help assess its role in the changing occurrence of non-Hodgkin's lymphoma, are not available. In the United States, however, current estimates of the percentage of women who have used or are using hair coloring products range from 20% (G. N. McEwen, Jr, personal communication, February 1991) to 40%.[49] The excess of non-Hodgkin's lymphoma in the present study is consistent with findings from the largest case-control study of this tumor and non-occupational hair dye exposure.[11] If it is causal, hair coloring product use would explain a larger percentage of non-Hodgkin's lymphoma cases among women than any other currently known or suspected risk factor. □

In: Catania JA, Coates TJ, Kegeles S, et al. Condom use in multi-ethnic neighborhoods of San Francisco: the population-based AMEN (AIDS in Multi-Ethnic Neighborhoods) study. *Am J Public Health* 1992;82:284–287.

Because of programming errors detected by the authors only after publication of the article, Tables 4, 5, and 6 provided some incorrect data. The corrected data are shown in the tables printed here.

The substantive conclusions based on the original tables have not changed with the exception that the "Other" condom-related beliefs measure is no longer a significant correlate of condom use for gay and bisexual men. Both the discussion and the abstract are correct as published in the original article. The authors regret the errors.

Education, Race, and High-Density Lipoprotein Cholesterol among US Adults

David S. Freedman, PhD, David S. Strogatz, PhD, David F. Williamson, PhD, and Ronald E. Aubert, PhD

ABSTRACT

Objectives. Although educational achievement is positively related to levels of high-density lipoprotein cholesterol (HDL-C) among White adults, there is an inverse association among Blacks. We assessed whether this interaction could be attributed to differences in the relation of education to correlates of HDL-C.

Methods. Cross-sectional analyses were based on data from 8391 White and 995 Black adults who participated in the Second National Health and Nutrition Examination Survey.

Results. Associations between education and HDL-C levels varied from negative (Black men), to nearly nonexistent (White men and Black women), to positive (White women). Mean HDL-C levels were higher among Blacks than among Whites, but differences varied according to educational achievement. Among adults with less than 9 years of education, mean levels were 6 to 10 mg/dL higher among Blacks, but the racial difference was less than 1 mg/dL among adults with at least 16 years of education. About 20% to 40% of these differences could be accounted for by obesity, alcohol consumption, and other characteristics.

Conclusions. Because of the implications for coronary heart disease risk, consideration should be given to behavioral characteristics associated with the interaction between race and educational achievement. (*Am J Public Health.* 1992;82:999–1006)

Introduction

Rates of coronary heart disease (CHD) in the United States are no higher among Black men than among their White counterparts[1–4] despite the higher prevalence of hypertension among Blacks.[5] These paradoxical findings may be due to differences in levels of high-density lipoprotein cholesterol (HDL-C): mean levels are about 20% (7 to 11 mg/dL) higher among Black men than among White men but are more similar between Black and White women.[4,6–9] Low levels of HDL-C have been shown, in several studies of White populations,[10] to increase the risk for CHD and are associated with more severe coronary artery disease among Black men.[11,12]

Levels of HDL-C are related positively to alcohol consumption and physical activity and inversely to obesity and cigarette smoking, but most information has been obtained from studies of White populations.[13,14] Although HDL-C levels among Blacks are also related to alcohol consumption (positively) and Quetelet index (overweight) (negatively),[4,7,9] associations with socioeconomic status appear to differ between races. Whereas a positive association between HDL-C and various indicators of socioeconomic status is typically observed among Whites,[4,7,15] an inverse association has been reported among Blacks.[4,7,9,16]

The association between socioeconomic status and levels of HDL-C may, in part, be mediated by behavioral characteristics.[15] In agreement with this hypothesis, we have found that the Black/White difference in the association between educational achievement and levels of HDL-C among 31- to 45-year-old male veterans could, in part, be attributed to relative weight, cigarette smoking, and alcohol consumption.[9] The objectives of the current study are to (1) assess these findings in an independent sample, (2) extend these observations to women and to older men, and (3) incorporate information on additional characteristics such as physical activity and body fat distribution. Data are from a representative sample of US adults who participated in the Second National Health and Nutrition Examination Survey (NHANES II).

Materials and Methods

Study Population

Information concerning various risk factors for CHD and the sample of adults with HDL-C determinations in NHANES II, a multistage survey, has been described.[7] Data were collected between 1976 and 1980 by the National Center for Health Statistics through standardized interviews and physical examinations.

Of the 20- to 74-year-olds comprising the original sample of 17 058 persons, 88% (n = 15 080) were interviewed and 68% (n = 11 637) were interviewed and examined. An investigation of possible selection biases[17] indicated that nonresponse at the interview stage did not vary according to the sex or race of the head of household,

but participation was lower for urban subjects than for those in more rural areas (86% vs 93%). Although persons with self-perceived health problems were more likely to be examined, the assessed health status of participants was comparable to that of subjects in the National Health Interview Survey, which had a 4% nonresponse rate.[17] Race, education, and income did not differ between examined and nonexamined persons in NHANES II.

Of the 11 637 adults examined in NHANES II, HDL-C determinations were performed for 83% (n = 9625), yielding an overall response rate of 56.4% of the original sample. The proportion of examined persons with HDL-C levels varied by race (Whites, 83%; Blacks, 78%) but not by sex, educational achievement, income, age, alcohol consumption, cigarette smoking, or several other characteristics.[7]

Risk-Factor Information

We used educational achievement, determined by the highest attended grade, as an indicator of socioeconomic status. As compared with indices such as income and occupation, education remains fairly constant throughout adulthood, is available for nonemployed and retired persons, and is unaffected by illness. HDL-C levels were related similarly to income and educational achievement in NHANES II.[7]

Race was determined by interviewers' observation or direct questioning. About 4% (n = 339) of White adults indicated they were of Hispanic descent, with Mexicans and Mexican Americans representing the largest subgroup (n = 196). Although most analyses did not distinguish between Hispanic Whites and non-Hispanic Whites, the former were excluded from certain sensitivity analyses.

Quetelet index (kg/m^2) and skinfold thickness measurements were used as measures of overweight and obesity, respectively. The ratio of subscapular to triceps skinfold thickness, an index of central (truncal) fat, was used to describe body fat distribution. Interviewees were asked two questions concerning physical activity: (1) were they getting "much," "moderate," or "little or no" recreational exercise? and (2) aside from recreation, were they usually "very active," "moderately active," or "quite inactive"? These responses were dichotomized as very active/much exercise versus other responses in some analyses.

Self-reported information was used for several prevalent diseases and medications. Diabetes mellitus was defined by positive responses to two questions: "Do you have diabetes or sugar diabetes?" and "Did a doctor tell you this?" Oral contraceptive use was ascertained through the question, "Have you taken birth control pills in the last 6 months and are you taking them now?" Women who reported taking hormones within the last week were considered to be using estrogens. Use of steroids, cholesterol-lowering drugs, and hydantoins was also determined from questions concerning use within the previous week.

Subjects were asked about their usual consumption of beer, wine, and liquor over the previous 3 months, and the number of weekly drinks (summed over the three alcohol categories) was calculated. Cigarette smoking was also assessed, and the reported number of cigarettes smoked daily was used in the analyses. Data on intake of total calories and saturated fats were collected through 24-hour dietary recalls, and subjects were asked if the foods were representative of their usual diet.

Serum Lipid Determinations

About 50% of the examinees were fasting at the time of examination, and in a sample of adults with an oral glucose tolerance test, mean levels of total cholesterol differed by 3 mg/dL or less between fasting and nonfasting persons.[18] Serum was frozen within 1 hour of collection, and specimens were shipped (at approximately 2-week intervals) for lipid analyses to the Lipid Research Clinics Laboratory at George Washington University. Analyses were performed according to standardized protocols,[19] with HDL-C assayed using a heparin and manganese chloride precipitation method.

Statistical Methods

Of the 9625 subjects with HDL-C measurements, persons were excluded if data were missing for one or more of the following characteristics: years of education (n = 85), subscapular (n = 88) or triceps (n = 24) skinfolds, weight or height (n = 51), number of daily cigarettes (n = 14), or alcohol consumption (n = 15). These restrictions resulted in a sample size of 9386 adults (8391 White, 995 Black) for most analyses. Persons were excluded from analyses that used data from the 24-hour dietary recalls if the reported foods did not represent their usual diet (n = 3503) or if their caloric intake was less than 500 kcal or 6000 kcal or more (n = 214).

All analyses incorporate the weights and complex sampling design of NHANES II, with variances calculated using SESUDAAN.[20] After levels of various characteristics between Blacks and Whites were contrasted, associations among various characteristics were examined using linear regression (SUREGR)[21] and stratification. A Race [0 (Whites), 1 (Blacks)] × Education interaction term was incorporated into several analyses as an independent variable. Because education and age were inversely associated, analyses were age adjusted with age treated as a six-level categorical variable: 20–24, 25–34, 35–44, 45–54, 55–64, and 65–74 years.

Several analyses were performed to determine if the observed interaction between race and education could be "explained" by other characteristics. The magnitude of the Race × Education term in regression analyses was compared before and after inclusion of (1) all covariates and (2) each covariate separately. All *P* values and confidence intervals are two-sided.

Results

Mean levels of age and total cholesterol varied only slightly across race-sex groups, but HDL-C levels were higher among Blacks than among Whites (Table 1), with differences of 7 mg/dL among men and 3 mg/dL among women. Whites were more likely to have had some education beyond high school (e.g., 41% of White men vs 26% of Black men) and an income greater than $20 000 per year.

Race-related differences were also observed for other characteristics. Compared with White women, Black women were more obese and had a more central distribution of body fat, as estimated by the ratio of subscapular to triceps skinfolds. Among men, Blacks also had a more central fat distribution than did Whites despite having a *lower* mean Quetelet index. Blacks were also more likely to smoke cigarettes, but Black smokers reported a smaller number of daily cigarettes than did White smokers. Blacks tended to be more physically active and to have lower daily intakes of total calories and saturated fats than did Whites. Differences in the prevalence of diabetes and in the use of oral contraceptives and sex hormones were also observed.

The relation of educational achievement to levels of HDL-C is shown in Figure 1. (Because education and age were inversely associated [$r = -0.29$ to -0.55], mean levels of HDL-C have been age

TABLE 1—Differences in Mean Levels of Various Characteristics between Blacks and Whites in Sample

	Men		Women	
	Whites (n = 3938)	Blacks (n = 443)	Whites (n = 4453)	Blacks (n = 552)

(% of kcal)	13 ± 5	−1 (−2, 0)	13 ± 5	0 (−1, 0)

[a]Values are mean ± standard deviations; the complex sampling design was accounted for in the calculation of the standard deviations.
[b]Values are Black–White difference in mean levels, with 95% confidence interval (CI) shown in parentheses. A positive value indicates that mean levels are higher among Blacks than among Whites.
[c]Restricted to current drinkers (n = 5677) or current smokers (n = 3221).
[d]High (or "much") category versus moderate/little.
[e]Restricted to the 5774 (2567 White men, 274 Black men, 2613 White women, and 320 Black women) subjects who reported consuming their usual diet.

adjusted.) Among White men, mean HDL-C levels varied only slightly with education, but there was a 7 mg/dL decrease over the five education categories among Black men. The relation also differed between Black and White women, with a positive association seen among Whites only. Within each sex, Black/White differences in mean levels of HDL-C were less than 1 mg/dL among persons with at least 16 years of education. Additional analyses treating education as a continuous variable indicated that the Black excess in HDL-C levels decreased by 0.6 mg/dL (women) to 0.7 mg/dL (men) with each additional year of education; the Race × Education interaction term was statistically significant among men ($P = .004$) and women ($P = .02$).

Cross-sectional associations between levels of HDL-C and other characteristics are shown in Table 2; values represent the predicted change in HDL-C for a specified change in each variable. For example, with each additional year of education, levels of HDL-C were estimated to change by +0.8 mg/dL among White women, by +0.2 mg/dL among White men and Black women, and by −0.5 mg/dL among Black men. Levels of HDL-C were inversely associated with obesity and, with the exception of Black men, with the amount of centrally located body fat. As expected, HDL-C levels were positively related to alcohol consumption, but an inverse association with cigarette smoking was seen among Whites only. Physical activity tended to be positively related to levels of HDL-C. Neither total calories nor saturated fats was associated with levels of HDL-C among men, but weak, positive associations were seen in women.

Several of the dichotomous variables were also associated with HDL-C levels, with higher mean levels seen among hydantoin users and women using sex hormones. Although associations with cholesterol-lowering drugs were inconsistent, the mean level of HDL-C was 17 mg/dL lower among the two Black men who reported using these medications than among other Black men. Mean levels of HDL-C were also lower among diabetics (vs nondiabetics) and among the 10 men who reported using steroids (data not shown).

Associations between education and various characteristics were then examined, and several could possibly account for the interaction between race and education. Among men (Table 3), levels of Quetelet index and subscapular skinfold thickness increased with educational achievement among Blacks but not among Whites. In addition, associations with alcohol consumption, cigarette smoking, dietary intake of total calories and saturated fat, and diabetes also differed between Whites and Blacks. Among men with at least 16 years of education, Blacks were more obese, had a higher prevalence of diabetes, and consumed less alcohol than did Whites.

Among women (Table 4), education showed a stronger (inverse) association with overweight and obesity among Whites than among Blacks. For example, Blacks who had completed up to 8 years of education were, on average, 2 kg/m² heavier than their White counterparts, but the difference increased to 3.9 kg/m² among women with at least 16 years of education. Alcohol intake was positively associated with education among White, but not Black, women. Positive associations with saturated fat intake and use of oral contraceptives and sex hormones were stronger among Blacks than among Whites.

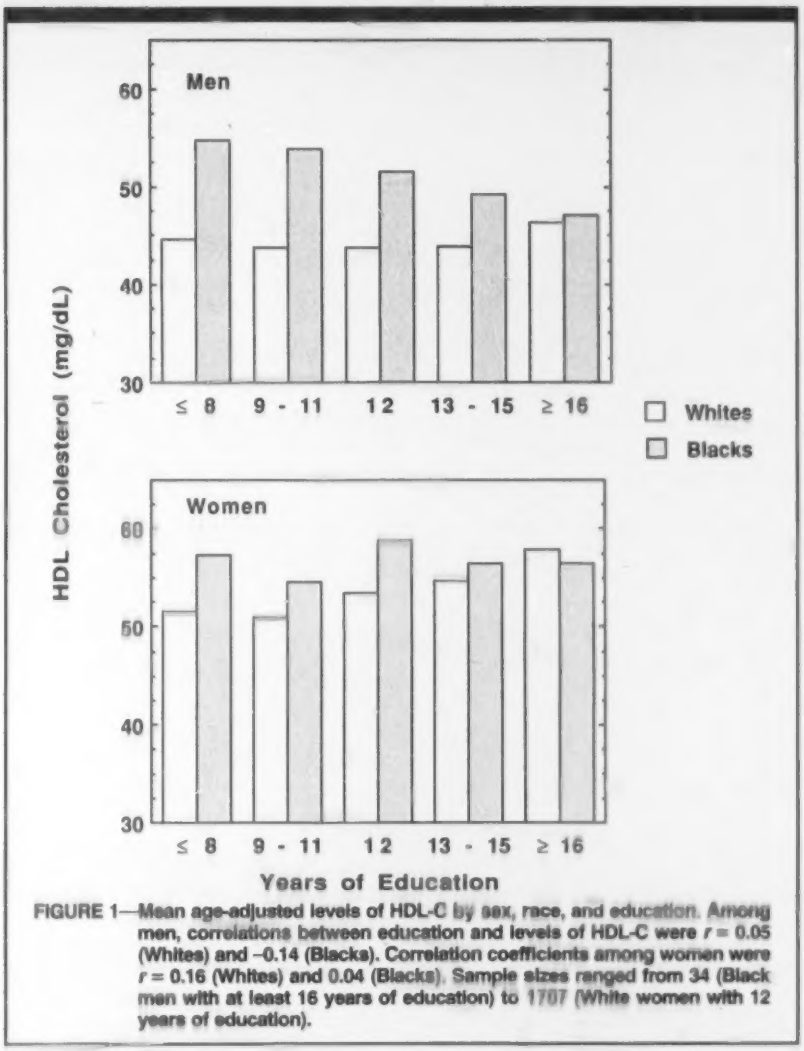

FIGURE 1—Mean age-adjusted levels of HDL-C by sex, race, and education. Among men, correlations between education and levels of HDL-C were $r = 0.05$ (Whites) and –0.14 (Blacks). Correlation coefficients among women were $r = 0.16$ (Whites) and 0.04 (Blacks). Sample sizes ranged from 34 (Black men with at least 16 years of education) to 1707 (White women with 12 years of education).

Analyses were then performed to determine whether the interaction between race and education was attributable to the covariates. Coefficients and predicted differences (Black–White) in HDL-C levels from two regression models are shown in Table 5. Independent variables in model #1 include race, education, race × education, and age; model #2 contains, in addition to these variables, obesity, alcohol consumption, cigarette smoking, and other characteristics. Adjusting for the additional covariates reduced the coefficient of the race × education interaction term by 19% (from –0.72 [model #1] to –0.58 [model #2]) among men and by 41% (from –0.56 to –0.33) among women. Age-stratified analyses indicated that the covariates were important among both younger and older adults (less than 45 years old and 45 to 74 years old, respectively) in accounting for the Race × Education interaction. Most of the variability in levels of HDL-C remained unexplained, however, with the multiple correlation coefficient (R^2) reaching a maximum of 0.18.

Additional analyses, comparable to those shown in Table 5, were performed to examine the effects of various exclusions and individual variables (data not shown). After the 339 Hispanic Whites were excluded, reductions in the magnitude of the Race × Education interaction between the two models were similar to those shown in Table 5. As assessed by analyses in which each characteristic was added separately to model #1, subscapular skinfold thickness and alcohol consumption were the most important covariates in accounting for the observed interaction. Furthermore, covariate adjustment reduced the absolute magnitude of the association between levels of HDL-C and education within each race-sex group. For example, the predicted change in levels of HDL-C with each year of education was reduced from +0.8 to +0.5 mg/dL (White women) and from –0.5 to –0.3 mg/dL (Black men) after controlling for alcohol consumption and subscapular skinfold thickness.

Discussion

Our results indicate that differences between Blacks and Whites in the cross-sectional association between educational achievement and levels of HDL-C can, in part, be attributed to behavioral characteristics. Consistent with the results of other investigations,[4,6,9] mean levels of HDL-C were 3 mg/dL (women) to 7 mg/dL (men) higher among Blacks than among Whites. The largest Black/White differences in HDL-C levels were seen among adults with up to 8 years of education, whereas no difference was evident among persons with at least 16 years of education. With each additional year of education, mean HDL-C levels decreased by 0.5 mg/dL among Black men but not among White men ($\beta = +0.2$ mg/dL per year of educational achievement); among women, the association was positive among Whites ($\beta = +0.8$) but very weak among Blacks ($\beta = +0.2$). About 20% (men) to 40% (women) of the interactions between race and education could be accounted for by other correlates of HDL-C levels, particularly obesity and alcohol consumption.

Although only 56% of the original sample for NHANES II had an HDL-C determination, there were no differences in (1) interview status according to race or sex of the head of household,[17] (2) participation in the examinations by education or income,[17] or (3) obtainment of an HDL-C measurement according to levels of education, Quetelet index, alcohol consumption, or smoking status.[7] It is possible, however, that associations among race, educational achievement, HDL-C levels, and the explanatory variable may be biased by other factors related to participation. The similarity of many of our findings with those from other studies, however, makes this less likely.

With increasing industrialization, the burden of CHD appears to shift to lower social strata,[22] and persons with high socioeconomic status are no longer at the greatest risk.[1,23–26] It has been suggested[27] that these temporal changes occur because persons with high socioeconomic status can more quickly adopt detrimental behaviors that influence CHD risk and are

		2	0.17	0.3	–0.27	9.5	6.2	5.1

Note. R^2 = multiple correlation coefficient.
[a]All analyses are restricted to subjects with complete information for all characteristics; eight men and six women have been excluded.
[b]Race is coded as 0 (Whites) or 1 (Blacks) in the interaction term; education is coded as an ordinal variable with 18 levels. The regression coefficient for race is indicated by the Black excess in HDL-C levels for adults with 0 years of education.
[c]The dependent variable in all analyses is HDL-C. Model 1 contains race, education, race × education, and age as predictor variables. Model 2 contains, in addition to the variables included in model 1, Quetelet index; subscapular skinfold thickness; alcohol consumption; cigarette smoking; work-related physical activity; nonwork-related physical activity; diabetes; and use of hydantoins, cholesterol-lowering drugs, hormones (women only), oral contraceptives (women only), and steroids (men only).

then able to modify these behaviors more rapidly. Consistent with this hypothesis, the relation of socioeconomic status to levels of total cholesterol, cigarette smoking, and consumption of various foods has changed between the 1950s and 1980s.[23,28] Inverse associations between indicators of socioeconomic status and several CHD risk factors have been found,[15,23,28–30] and a positive association between educational achievement and levels of HDL-C has been reported in studies of White adults.[15,30]

In contrast, socioeconomic status was recently found to be *positively* related to CHD incidence among urban men in Puerto Rico, possibly due to the relatively recent economic development of this area.[31] Even within industrialized societies, however, the relation of socioeconomic status to CHD may vary across ethnic groups.[32] A study from one center in the Multiple Risk Factor Intervention Trial, for example, found that socioeconomic status was inversely related to a composite risk-factor score for CHD among White, Asian, and Hispanic men, but not among Black men.[33] Furthermore, a recent survey of adults from New York City found an inverse association between educational achievement and several CHD risk factors (smoking, sedentary behavior, obesity, and atherogenic diet) that was stronger among Whites than among Blacks.[34]

Our findings concerning the inverse association between educational achievement and levels of HDL-C among Black men agree with the results of other investigations. Mean HDL-C levels among Black adults from Framingham, Mass (50% of whom had completed college), were 6 to 7 mg/dL lower than those among Whites.[35] Black/White differences in the association between socioeconomic status indicators and levels of HDL-C have also been found in the Multiple Risk Factor Intervention Trial[4] and among US Army veterans.[9] With the exception of education, we found that associations between levels of HDL-C and most characteristics did not differ between Blacks and Whites. Although cigarette smoking was inversely associated with levels of HDL-C among Whites only, other studies of smoking and HDL-C levels in Blacks have yielded conflicting results, with the observed associations ranging from inverse[4] to weakly positive.[35]

Few studies have examined characteristics that might mediate the relation of educational achievement to levels of HDL-C. Heiss et al.,[15] however, in an analysis of White adults, found that most of the positive association between education and HDL-C levels among women could be attributed to obesity, alcohol consumption, smoking, and use of sex hormones. (Associations between education and these characteristics were similar to those seen in the current study.) Furthermore, about 40% of the interaction between race and educational achievement for levels of HDL-C could be attributed to Quetelet index, alcohol consumption, and cigarette smoking among 31- to 45-year-old men.[9] Our results, based on a national probability survey, extend these findings to women and older men. The persistence of a large proportion of the interaction even after covariate adjustment could result from (1) unmeasured characteristics that are associated with levels of HDL-C and educational achievement, or (2) misclassification of HDL-C levels and other characteristics. Because of the large day-to-day variability in dietary intake, our assessed intakes of total calories and saturated fat may be particularly inaccurate.

When one considers the differences in job opportunities, income, and physical environment that exist between Blacks and Whites at any specified level of education,[36] racial differences in the association between socioeconomic status and measures of health and health-related behaviors[37–40] are not surprising. A full explanation of Black/White differences in the association between educational achievement and levels of HDL-C remains to be resolved. Our findings, however, suggest that preventing obesity may be a useful goal for maintaining the relatively high levels of HDL-C seen among Blacks in the United States. □

Call for Abstracts for Primary Care Nursing Symposium

The 18th National Primary Care Nurse Practitioner Symposium is accepting abstracts of research, innovative clinical practice/models and roles, and other professional papers relating to primary care nursing. Sponsored by the University of Colorado Health Sciences Center School of Nursing, this symposium will be held July 8–11, 1993, at Keystone Resort, Keystone, Colorado.

Preference will be given to abstracts with strong clinical applicability, innovative role-development models, and a future-oriented perspective. Abstracts are being accepted for oral or poster presentation. Deadline for submission is *September 14, 1992.* Contact Ellen Lemberg, RN, MS, Nurse Practitioner Symposium Office, University of Colorado Health Sciences Center School of Nursing, 4200 East 9th Ave, Box C287, Denver, CO 80262; tel. (303) 270-7436.

Young Women's Antisocial Behavior and the Later Emotional and Behavioral Health of Their Children

Sandra L. Martin, PhD, and Margaret R. Burchinal, PhD

ABSTRACT

Objectives. Antisocial and criminal behavior are increasing among US youth, especially among females. Thus, questions arise concerning whether youthful female deviant behavior eventually will have negative behavioral and emotional consequences for the later children of these women.

Methods. Associations between the severity of early female antisocial behavior (including both drug-related and non–drug-related offenses) and the later behavioral and emotional health of the children of these women were examined among 1425 mother–child pairs of the National Longitudinal Survey of Youth.

Results. Multiple linear regression procedures indicated a significant positive relationship between the severity of the mothers' early non–drug-related offenses and the later severity of the children's scores on the Antisocial, Hyperactive, Anxious/Depressed, Headstrong, Peer Conflict/Social Withdrawal, Immature Dependency, and Total Problem subscales of the Behavior Problem Index.

Conclusions. This study demonstrated an association between the antisocial behavior of female youth and the later behavioral and emotional problems of the children of these women. Future research needs to determine the mechanisms underlying the intergenerational transmission of these types of problems so that effective preventive and therapeutic public health practices may be designed and implemented. (*Am J Public Health.* 1992;82:1007–1010)

Introduction

Antisocial and criminal behavior are on the upswing among US youth, especially among females.[1] This trend raises questions concerning whether youthful female deviant behavior will eventually have negative consequences for the later children of these women. Although ties have been established between female antisocial behavior and deviancy in the children of these women, research has tended to focus on the most antisocial of women, in particular, women who have been arrested or incarcerated. For example, studies have found that juvenile delinquents are more likely than nondelinquents to have mothers who have been involved with the law,[2–6] and a high prevalence of school behavior problems have been found in children of incarcerated women.[7] Furthermore, past research concerning the children of antisocial women has usually examined a restricted range of childhood problems, typically juvenile delinquency, ignoring other forms of childhood emotional and behavioral problems. In addition, these studies often have used small clinic samples of subjects rather than large samples of the general population.

In this study, we examine the association between the severity of early female antisocial behavior (including both drug-related and non–drug-related offenses) and the later behavioral and emotional health of the children of these women using a secondary data analysis of information from a nationwide prospective study of American youth, specifically, the National Longitudinal Survey of Youth (NLSY).

Materials and Methods

The National Longitudinal Survey of Youth

The NLSY began in 1979 as a prospective study of factors that influence the labor force participation of American young people.[8] The original cohort included both men and women, aged 14 to 24 years, with an overrepresentation of African Americans, Hispanics, and economically disadvantaged non-Hispanic Whites. Since the inception of the project, 1-hour personal interviews of cohort members have been conducted annually, with 95% of the sample being reinterviewed each year.

Interview content varies from year to year, with information being collected on a multitude of factors, including socioeconomic, sociodemographic, familial, health, and behavioral characteristics. During the 1980 interview, the Self Reported Delinquency Index[9] was used to assess the frequency of cohort participation in antisocial activities (e.g., vandalism, selling drugs). During the 1986 interview, female participants who were mothers of children at least 4 years of age were administered the Behavior Problem Index[10,11] to assess their children's emotional and behavioral health. Thus, linking the 1980 and 1986 NLSY interviews allows examination of the relationship between the antisocial behavior of female youth and the later emotional and behavioral health of the children of these women.

Sandra L. Martin is with the Department of Maternal and Child Health, and Margaret R. Burchinal is with the Department of Psychology and the Frank Porter Graham Child Development Center, University of North Carolina at Chapel Hill.

Fraud	264	19	5.16	9.59
Petty theft	132	9	2.80	5.52
Vandalism	110	8	2.35	3.74
Aggravated assault	108	8	2.81	5.95
Fencing stolen goods	83	6	3.34	7.68
Auto theft	72	5	3.96	8.07
Robbery	35	2	4.11	9.96
Grand theft	21	1	1.52	1.54
Break and enter	19	1	4.47	11.16
Run gambling operation	19	1	11.53	18.80

Sample Selection

Of the 1612 NLSY women who participated in the assessment of their children's behavioral and emotional health, 1425 (88%) had complete information available for all selected analysis variables for both the 1980 and 1986 interviews; therefore, these 1425 women and their first-born children were selected to be included in this study. Comparison of the 1425 women with complete information with the 187 women with incomplete information indicated no statistically significant differences ($P < .05$) in terms of the women's ethnicity, age, educational attainment, employment histories, marital status, number, age and gender of children, and children's scores on the emotional/behavioral assessments.

Assessment of the Women

The severity of the antisocial behavior of the women in 1980 was assessed using the Self Reported Delinquency Index.[9] This instrument is a listing of 16 specific antisocial behaviors (e.g., stealing items worth more than $50, selling hard drugs) to which the subject responds by noting the frequency of his or her participation in each of the behaviors during the past year (i.e., "never," "once," "twice," "three to five times," "six to ten times," "eleven to fifty times," and "more than 50 times"). Item scores are calculated by assigning the midpoint value of the first five response categories and assigning a score of 50 to those who responded in the "50 or more" category. Then, two summary indices, severity of drug offenses and severity of nondrug offenses, are created by summing the subject's scores to pertinent behavioral items and dividing by the number of items composing each index (see Table 1 for the offenses included in each summary index). For analysis purposes, a square root transformation was used on the severity indices to help suppress the effects of the few extreme outlying values of these predictor variables.

Care was taken in administering the Self Reported Delinquency Index to promote an environment in which the respondents would feel comfortable answering potentially sensitive questions (e.g., respondents were assured of confidentiality; respondents recorded their answers on separate response sheets rather than responding aloud to questions; respondents placed their completed response sheets within envelopes, which they then sealed). Despite the delicate nature of these questions, more than 98% of all subjects completed the assessment. Although it should be recognized that any self-report measure of antisocial behavior is likely to represent an underreport of the true prevalence of the behavior, studies of the Self Reported Delinquency Index, which compared the severity indices with information concerning police contact and school behavior problems, report good reliability and validity.[9]

The 1980 and 1986 interviews also collected information concerning the women's ethnicity, age, years of education, marital status, and poverty status. The poverty status of the women was assessed using modified federal guidelines based on income, family size, and residence.[12,13]

Assessment of the Children's Emotional and Behavioral Health

The emotional and behavioral health of the children was assessed in 1986 using the Behavior Problem Index (BPI).[10,11] This instrument is a listing of 28 specific childhood problem behaviors or symptoms, many items being drawn from previous scales.[14–17] The child's mother responds to each of the BPI items indicating whether the symptom in question has been typically exhibited by her child within the past 3 months. Positive responses to specific items are summed to create a Total Problem score and the following six empirically derived subscale scores: (1) Antisocial, (2) Hyperactive, (3) Anxious/Depressed, (4) Headstrong, (5) Peer Conflict/Social Withdrawal, and (6) Immature Dependency. The Total Problem score and the subscale scores have been standardized by age and gender based on general population samples (mean = 100, SD = 15). Reliability estimates of the Total Problem score range from .86 to .89, while those for the various subscale scores range from .54 to .73.[10]

Analysis

Linear regression analyses[18] were conducted to examine the potential associations between the mothers' severity of drug and nondrug offenses and their children's levels of emotional and behavioral problems. First, the children's BPI Total Problem scores were analyzed. Then, each of the five BPI subscale scores was analyzed. Three sets of predictor variables were used in the models. The first set consisted of the variables of interest, namely, the mother's severity of drug and nondrug offenses indices. The second set of predictors included sampling variables that had been used to select the original NLSY cohort, specifically, ethnicity (African American, non-Hispanic White, Hispanic), poverty (yes, no), and an ethnicity by poverty interaction term. The interaction term was necessary because the NLSY oversampled Hispanics, African Americans, and impoverished non-Hispanic Whites. The third set of predictor variables was selected to control for potential confounders. These variables included the mother's age at the time she

was asked about her antisocial behaviors, the marital status of the mother in 1986, the age of the child in 1986, and the gender of the child. F tests (with a type I error rate of .05) were used to evaluate all statistical tests. Effect sizes for the variables of interest were measured using estimated regression coefficients, and 95% confidence intervals were calculated.

Results

Description of the Women in 1980

The study women included 688 (48%) non-Hispanic Whites, 481 (34%) Hispanics, and 256 (18%) African Americans. Of these women, 496 (35%) were living in poverty in 1980. In 1980, the women ranged in age from 15 to 23 years, with the mean age being 19.58 years (SD = 2.03). Their ages at the birth of the target children ranged from 13 to 24 years (mean = 18.13, SD = 2.22). A total of 713 (50%) of the women were never married, 594 (42%) were married, and 118 (8%) were divorced or separated during 1980. The women's educational levels in 1980 ranged from 0 to 16 years, with the mean being 10.88 years (SD = 1.87).

The results of the Self Reported Delinquency Index showed that 257 (18%) of the study women committed at least one drug offense during 1980 (232 [16%] women used hard drugs, 75 [5%] sold marijuana, and 19 [1%] sold hard drugs). Over all 1425 women, the severity of drug offense index ranged from 0 to 45, with a mean of 0.82 (SD = 3.65).

A total of 814 (57%) study women committed at least one nondrug offense, the most common being assault (419 women; 29%), shoplifting (320 women; 22%), physically fighting at school or work (272 women; 19%), and fraud (264 women; 19%). Over all 1425 women, the severity of nondrug offense index ranged from 0 to 12.92, with a mean of 0.40 (SD = 1.08).

Description of the Women and Children in 1986

The poverty, marital, and educational status of the women remained fairly stable from 1980 through 1986. The poverty status of 71% of the study women remained the same from 1980 through 1986, with 37% of the study women living in poverty in 1986. The marital status of 61% of the women remained constant over the two time points, with 352 (25%) women never being married, 774 (54%) being married, and 299 (21%) being separated or divorced during the 1986 interviews. There was a significant correlation between the women's years of education in 1980 and 1986 (r = .88, P < .0001), with the mean education level of the women in 1986 being 11.30 years (SD = 2.01).

No information concerning drug offenses or nondrug offenses was collected during the 1986 assessment; thus, it cannot be determined whether the women's antisocial and drug-related behaviors remained consistent over the 6-year study period.

In 1986, the target children ranged in age from 4 years to 12 years (mean = 7.45, SD = 2.08), with girls and boys being fairly equally represented in the sample (735 boys [52%] and 690 girls [48%]). The children's mean BPI Total Problem score (mean = 108.8, SD = 13.7) and the means of all six BPI subscale scores (i.e., Antisocial [mean = 108.1, SD = 13.7], Hyperactive [mean = 109.2, SD = 13.8], Anxious/Depressed [mean = 106.8, SD = 13.1], Headstrong [mean = 103.6, SD = 13.1], Peer Conflict/Social Withdrawal [mean = 105.8, SD = 12.9], and Immature Dependency [mean = 106.7, SD = 13.2]) were above the general population mean of 100, perhaps reflecting the large proportion of high-risk families in this sample (e.g., financially deprived families).

When the children's BPI Total Problem scores were analyzed, a statistically significant effect was observed for the mother's severity of nondrug offenses, F(1, 1413) = 30.81, P <.0001, with the children's problem behavior increasing with increasing frequencies of the mothers' nondrug offenses; however, the mother's severity of drug offenses was not found to be significantly related to the children's BPI Total Problem scores. When the six BPI subscale scores were modeled, similar results were found in that severity of nondrug offenses was significantly associated with each of the children's BPI subscale scores: Antisocial, F(1, 1413) = 22.07, P <.0001; Hyperactive, F(1, 1413) = 19.83, P <.0001; Anxious/Depressed, F(1, 1413) = 18.13, P <.0001; Headstrong, F(1, 1413) = 17.35, P <.0001; Peer Conflict/Social Withdrawal, F(1, 1413) = 9.77, P = .0018; and Immature Dependency, F(1, 1413) = 7.20, P = .0074. However, the severity of drug offenses was not significantly related to any of the six BPI subscale scores.

TABLE 2—Estimated Regression Coefficients and Associated 95% Confidence Intervals

Behavior Problem Index Score	Regression Coefficients (95% CI)	
	Drug Offenses	Nondrug Offenses
Total Problem	−0.49 (−1.39, 0.41)	4.27 (2.76, 5.78)
Antisocial	−0.02 (−0.87, 0.91)	3.58 (2.09, 5.06)
Hyperactive	−0.37 (−1.27, 0.53)	3.44 (1.93, 4.95)
Anxious/Depressed	−0.38 (−1.24, 0.48)	3.15 (1.70, 4.60)
Headstrong	−0.52 (−1.37, 0.33)	3.03 (1.61, 4.45)
Peer Conflict/Social Withdrawal	−0.41 (−1.27, 0.45)	2.29 (0.85, 3.73)
Immature Dependency	−0.18 (−1.04, 0.72)	2.01 (0.54, 2.94)

Table 2 presents the estimated regression coefficients and 95% confidence intervals associated with the two variables of interest, severity of drug offenses and severity of nondrug offenses, for each of the models of the children's BPI Total Problem and subscale scores. There is no significant association between the mother's severity of drug offenses and any of the children's BPI scores; however, each of the children's BPI scores tends to increase significantly with increasing levels of the mother's severity of nondrug offenses. It is interesting that the largest effect size relating the mother's severity of nondrug offenses and the children's BPI subscale scores occurs in the model of the children's Antisocial scores.

Discussion

In line with previous research that has demonstrated a link between female criminality and deviancy in the children of these women, this study found an association between the antisocial behavior of female youth and the later behavioral and emotional problems of the children of these women. This study extends past research by examining a range of severity of women's antisocial behaviors and a range of children's behavioral and emotional problems. Specifically, the present study found a positive relationship between the severity of antisocial behavior of female youth and the severity of behavioral and emotional problems of the children of these women 6 years later. This relation-

ship was found for non–drug-related offenses but not for drug-related offenses. However, some explanations and cautionary comments are in order.

First, one must interpret the results of this research with caution given the limitations of both the study design and the correlational nature of the study analysis. The observed association between the severity of women's antisocial behavior and the severity of their children's emotional and behavioral problems is likely due to life-style differences, which tend to be established by the teenage years. These lifestyle differences may be due to unobserved familial and social factors, such as family dysfunction, living in a high-crime neighborhood, and so forth. Thus, it is impossible from this study to specify the potential causal chain that connects the life experiences of adolescent females through to the later emotional and behavioral health of the children of these young women. Future studies of this topic need to concentrate on understanding the specific mechanisms underlying the intergenerational transmission of these types of problems.

Second, one must consider the fact that the measure of the women's drug and nondrug offenses and the measure of the children's emotional health occurred at two separate time points, with approximately 6 years between the two assessments. Therefore, we are unsure whether the early antisocial behavior and drug use of the women remained stable over the 6-year period. Furthermore, many unmeasured events might have occurred during that 6-year period that might have affected the children's emotional and behavioral development. In light of these considerations, it is interesting that we still see an association between the early behavior of the women and the later emotional and behavioral health of their children. However, this finding is not totally unexpected since research has suggested some degree of continuity in values and behaviors from adolescence through to early adulthood.

Third, the measures of female antisocial behavior and children's emotional and behavioral health were based on reports of the study women. As such, they are subject to the biases associated with self-report data.

Fourth, it is noteworthy that we did not find an association between the women's severity of early drug-related offenses and their children's later behavioral and emotional health, while we did find such a relationship when the women's non–drug-related offenses were examined. Further study of the data sheds some light on this finding. Of the 1425 study women, 568 reported committing neither drug nor nondrug offenses, 214 reported committing both drug and nondrug offenses, and 600 reported committing exclusively non–drug offenses; however, only 43 reported committing exclusively drug offenses. In other words, most of the drug offenders also committed nondrug offenses, while only about a third of the women who reported nondrug offenses also reported committing drug offenses. Therefore, the ability of this study to detect a potential effect of drug offenses, independent of that of nondrug offenses, may have been somewhat limited by the relatively small size of the drug offenses alone group.

In spite of the aforementioned study limitations, the findings do suggest some interesting paths for future investigation concerning the potential intergenerational transmission of behavioral and emotional problems. Gaining greater insight concerning the mechanisms underlying the relationship between parents' and children's emotional and behavioral health could, we hope, lead to the design and implementation of effective preventive and therapeutic public health policies aimed at enhancing the health of both parents and children. □

Rotating Shift Work, Sleep, and Accidents Related to Sleepiness in Hospital Nurses

Diane R. Gold, MD, MPH, Suzanne Rogacz, MD, Naomi Bock, MD, MS, Tor D. Tosteson, DSc, Timothy M. Baum, MS, Frank E. Speizer, MD, and Charles A. Czeisler, PhD, MD

ABSTRACT

A hospital-based survey on shift work, sleep, and accidents was carried out among 635 Massachusetts nurses. In comparison to nurses who worked only day/evening shifts, rotators had more sleep/wake cycle disruption and nodded off more at work. Rotators had twice the odds of nodding off while driving to or from work and twice the odds of a reported accident or error related to sleepiness. Application of circadian principles to the design of hospital work schedules may result in improved health and safety for nurses and patients. (*Am J Public Health.* 1992;82:1011–1014)

Introduction

Concern for iatrogenic risks to patients caused by hospital staff experiencing sleep disruption has led to a reexamination of the work schedules and sleep patterns of physicians.[1–4] This cross-sectional study was designed to examine the impact of work schedule on the sleep schedule, sleepiness, and accident rates of female nurses in a Massachusetts hospital.

Methods

A self-administered questionnaire was distributed June through September 1986 to 878 registered nurses, licensed practical nurses, and other ancillary staff in the hospital. The nurse was asked to record, for the current week, the previous 2 weeks, and the following week, the number of shifts worked for each work-shift category (i.e., day, evening, night) at the hospital and at any other job. The nurse was also asked, "Does your job involve a variable work shift? That is, do you work the day shift sometimes and the night shift at other times?," which is a National Center for Health Statistics (NCHS) question previously used to identify shift workers in the US population.[5,6] In addition, the nurse recorded her sleep and wake times when she worked the day shift, the evening shift, the night shift, and on days off.

Information was collected regarding: quality of sleep; the use of alcohol (per month), prescription or nonprescription medication, sleeping aids, or other kinds of drugs to get to sleep; nodding off at work (per week); nodding off while driving to or from work in the past year; and accidents, errors, and "near-miss" accidents in the past year. The variable "any accident or error" included automobile accidents, medication errors, on-the-job procedural errors, and on-the-job personal injuries that the nurse reported had occurred because of sleepiness.

We used prior hypotheses based on physiologic and epidemiologic data regarding shift work and circadian disruption[7–17] in the definition of shift categories (Table 1), which were created from shift schedules for the current month. Day/evening shift work was grouped as a single category because shifting from days to evenings has not been demonstrated to disrupt circadian rhythms.

Sleep and wake times were used to determine whether a nurse obtained "anchor sleep": at least 4 hours of sleep obtained regularly during the same clock hours every night, both during work days and days off. Studies by Minors and Waterhouse[18] suggest that loss of anchor sleep may be a surrogate for circadian rhythm disruption.

The relationship between shift and outcomes such as sleepiness and accidents was explored first through univariate and then through multivariate analy-

TABLE 1—Work Schedule Categories of Nurses Surveyed

Day/evening (n = 336): Within a month, working ≥ 4 day or evening shifts but no night shifts.
Night (n = 69): Within a month, working ≥ 8 night shifts and no day/evening shifts.
Rotator (n = 119): Within a month, working ≥ 4 day or evening shifts and ≥ 4 night shifts.
Day/evening, occasional night (n = 61): Within a month, working ≥ 4 day or evening shifts and 1–3 night shifts.
Night, occasional day/evening (n = 14): Within a month, working ≥ 8 night shifts and 1–3 day or evening shifts.
Part-time rotator (n = 17): Within a month, working 4–7 night shifts and 0–3 day or evening shifts.

ses, using EPISTAT and SAS (proc logistic). We attempted to validate the reporting of medication errors, but this was not possible because written accident reports submitted to the hospital's risk management office usually documented the nursing supervisor rather than the nurse associated with the error.

Results

Of 878 hospital employees contacted by the research assistants, 687 (78.3%) returned the questionnaire, 36 (4.1%) refused to participate, and 155 (17.7%) failed to return the questionnaire. The study cohort included 593 female registered nurses and 42 female licensed practical nurses.

The mean age of the nurses was 33.9 years (range 21 to 65 years). When compared to day/evening nurses, more rotators were 35 years old or younger (77.8% versus 64.5%). By contract, the option of not rotating and not working the night shift was dependent on seniority. Consequently, whereas 23.7% of rotators and 22.1% of night nurses had worked at the hospital for 1 year or less, only 9.3% of day/evening nurses had done so.

During their work days, rotators and night nurses reported fewer hours of sleep than day/evening nurses (Figure 1). Of the day/evening nurses, 92.2% obtained anchor sleep regularly throughout the month. In contrast, only 6.3% of night nurses, none of the rotators, and none of the nurses in work categories 4 through 6 (Table 1) obtained anchor sleep regularly throughout the month.

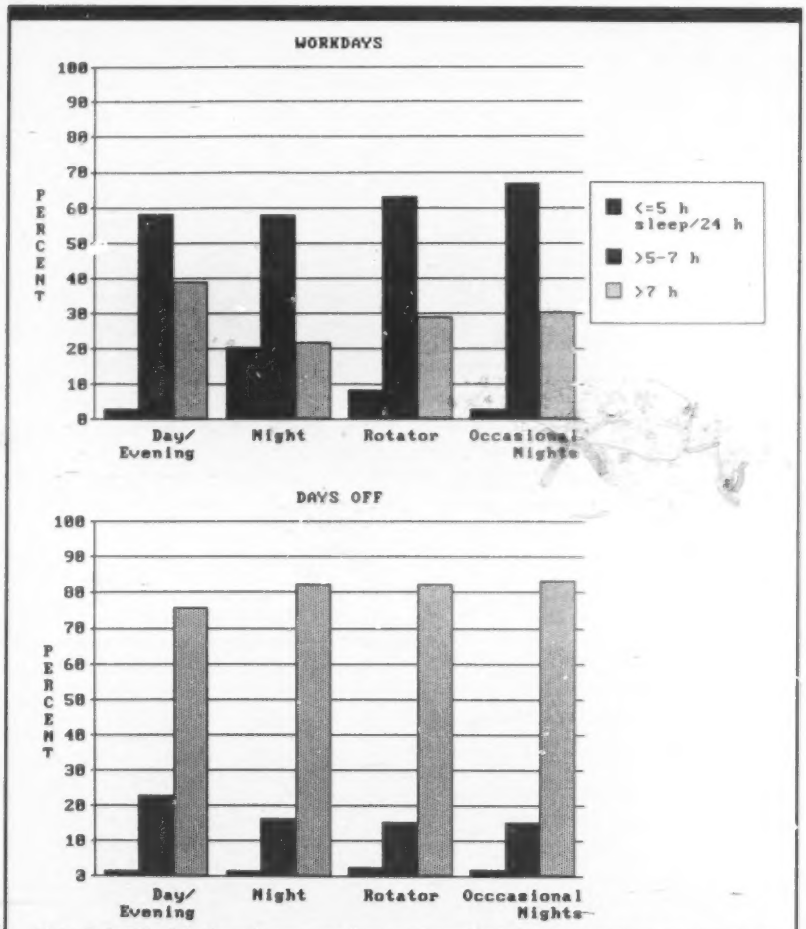
Of the nurses from all work categories who responded "yes" to the NCHS question on variable work schedules, only 53.6% experienced anchor sleep disruption. The group responding "yes" included 49.4% of the day/evening nurses, 94.1% of rotators, and 2.9% of night nurses.

In comparison to day/evening nurses, night workers had 1.8 times the odds and rotators had 2.8 times the odds of reporting poor quality sleep (Table 2). Night nurses and rotators had twice the odds of using medications to get to sleep.

Nodding off on the night shift occurred at least once per week in 35.3% of rotators, 32.4% of night nurses, and 20.7% of day/evening nurses who worked occasional nights. On the other hand, neither day/evening nurses nor rotating nurses reported significant problems with nodding off on the day or evening shift (rates for nodding off: 2.8% and 2.7%). When compared to day/evening nurses, rotators had 3.9 times the odds and night nurses had 3.6 times the odds of nodding off while driving to or from work in the preceding year (Table 2).

In univariate analyses two confounders of the relationship between shift and accidents were identified: working at the hospital 1 year or less was associated with medication errors, and an age of 35 years or younger predicted automobile near-miss accidents. The use of alcohol to get to sleep was an independent predictor of all categories of accidents.

Adjusting for these factors, the odds of reporting any accident or error were twice as high for rotators as for day/evening nurses (Table 3). Rotators had 2.5 times the odds of reporting near-miss accidents. After adjustment the effect of ro-



Note. Only 3% of day/evening nurses slept ≤ 5 hours/24 hours on workdays, as compared to 8% of rotators and 20% of night nurses. Less than 50% of nurses from each of the work schedules slept >7 hours/24 hours on workdays. On days-off greater than 75% of nurses from each of the work schedules slept >7 hours/24 hours.

*$P \leq 0.05$.

tating on medication errors was reduced from 2.2 (95% CI: 1.0, 4.9) to 1.8 (Table 3).

Discussion

The results of this study are consistent with laboratory investigations that have demonstrated that sleep deprivation and misalignment of circadian phase as experienced during rotating shift work are each associated with frequent lapses of attention and increased reaction time, leading to increased error rates on performance tasks.[7–9] These data also suggest that a record of a representative work schedule may be of greater use than the NCHS variable shift question in identifying workers with disrupted sleep/wake patterns.

Reporting bias and selection bias may have influenced the findings in this cross-sectional study. The hypotheses generated might be best tested through a case-control study design, with validation of reported accidents.

The data present a potential dilemma for hospital policymakers. Even if rotating leads to circadian rhythm disruption and accidents, nurses and hospital administrators will have to determine their priorities: the family responsibilities of nurses and the staffing requirements of hospitals may limit the potential for altering hospital schedules to improve the health of nurses and the safety of patients.[19,20] □

Acknowledgments

This research was supported in part by National Institutes of Health research and training grants NICHHD 5-R01-HD20174 and NHLBI 5-T32-HL07427 (Gold and Tosteson) and 5-MOI-RRO2635 (Rogacz).

We would like to acknowledge the enthusiastic participation of the hospital nurses, nursing administrators, and Department of Risk Management and Loss Control personnel in this research project. We are grateful to Mr. Joseph Ronda for assistance in data management and to Ms. Darlene Bramble for secretarial assistance.

Birthweight Distributions in Mexico City and among US Southwest Mexican Americans: The Effect of Altitude

Francis C. Notzon, PhD, José Luis Bobadilla, MD, PhD, and Irma Coria, MPH

ABSTRACT

In this study birthweight distributions for Mexican Americans and Mexico City were compared. Sharp differences in the two distributions were nearly eliminated by controlling for altitude. The small remaining excess in low birthweight in Mexico City appears to be due to a slight overrepresentation of tertiary hospital deliveries, and possibly to a greater prevalence of pathological conditions. The results are consistent with the favorable low birthweight rate reported for Mexican Americans and illustrate the need to adjust for altitude in studies of low birthweight. (*Am J Public Health.* 1992;82:1014–1017

Introduction

Low birthweight rates (birthweight <2500 g) vary widely with racial or ethnic origin.[1–3] However, these differences are attributed primarily to socioeconomic conditions strongly associated with these groups,[4–6] leading to the assumption that the more socioeconomically disadvantaged groups are the most likely to have low birthweight babies. Low socioeconomic status often is associated with factors known to impair the rate of fetal growth, such as inadequate nutrition and smoking.[7] Insufficient prenatal care and other factors also may mediate between low socioeconomic status and low birthweight.[4] While the association between socioeconomic status and ethnicity appears to hold for US Blacks and Puerto Ricans, this is not so for Mexican Americans.

The low birthweight rate for Mexican Americans is similar to that of US Whites, despite low socioeconomic status and poor access to prenatal care, and is far lower than the rate for US Blacks or Puerto Ricans (Table 1). This phenomenon, described as a "public health enigma," is not readily explainable.[8] Nevertheless, the low birthweight rate of Mexican Americans is so dramatically different from other US minority groups that a verification of the accuracy of the Mexican-American rate is warranted.

One approach to verifying these data is to compare Mexican-American birthweights with those found in Mexico. If

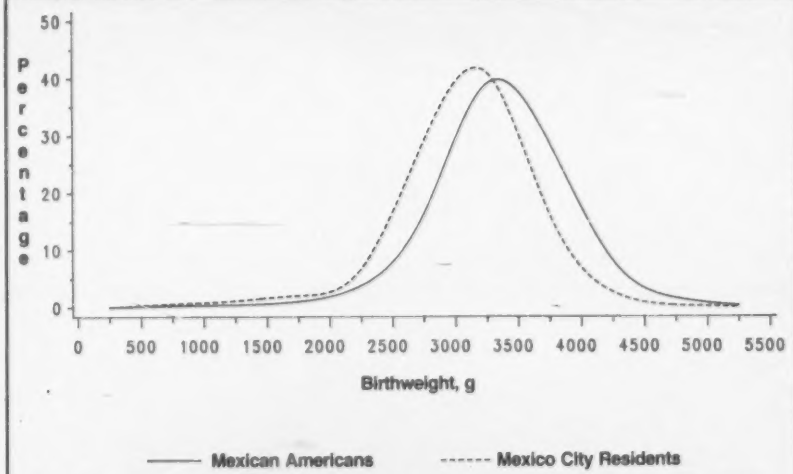

FIGURE 1—Birthweight distributions: US Southwest Mexican Americans, 1980–1984, and Mexico City Residents, 1984. Sources: US National Center for Health Statistics, national vital statistics data, 1980–1984; Mexico City, Center for Public Health Research, perinatal mortality study, 1984.

Mexican-American birthweights truly are not strongly affected by adverse health care and economic circumstances, then one would expect to find a roughly similar birthweight distribution in Mexico, at least in the more economically advanced areas. Genetic differences between Mexican Americans and Mexicans should be small, and behavioral factors such as low usage levels of tobacco, alcohol, and illegal drugs are common to both groups and likely to be lower for Mexican women.[9]

While accurate and complete information on birthweight is not available for the total population of Mexico, a 1984 study collected such data on births in Mexico City.[10] However, inhabitants of Mexico City reside at an altitude of 2200 m (about 7200 ft), while US Southwest Mexican-American births occur primarily at elevations below 500 m (about 1600 ft).

This study compares birthweight distributions for these two groups, using information on altitude of county of residence to adjust for differences in elevation between the two populations.

Materials and Methods

Information on Mexican-American births was obtained from US vital statistics for five southwestern states (Arizona, California, Colorado, New Mexico, Texas) for the years 1980 through 1984. These states contain 92% of all Mexican-American live births registered in the United States.[2] Vital statistics for the years 1980 through 1984 were combined into a single file, including about 1.1 million live births to women of Mexican-American or other Spanish origin in these states.

Information on the mean altitude of each county in the five-state area was obtained from the Bureau of Health Professions Area Resources File.[11] Sufficient numbers of Mexican-American births were available to permit determination of birthweight measures at 500 m gradations, up to the range of 2000 to 2499 m.

Information on births in Mexico City came from a 1984 study of the quality of medical care and perinatal mortality in Mexico City hospitals conducted by the Mexican Ministry of Health.[10] The study collected information on 32 760 live births occurring during May through August 1984 in 25 hospitals in the Federal District of Mexico (37% of all hospital births in Mexico City). Extensive quality-control measures were undertaken to ensure that birthweights were accurately recorded for all births.

Sample hospitals were selected from all Mexico City hospitals, stratified by health care agency (public assistance, social security, and private) and, for social security hospitals, by level of care. The resulting sample can be considered as approximately representative of all hospital births in Mexico City, although tertiary hospital births are slightly overrepresented.

The overwhelming majority of births in Mexico City in the 1980s occurred in hospitals. The National Fertility and Health Survey (1987) found that about 97% of Mexico City births between 1982 and 1986 were delivered by a medical doctor, and almost all occurred in hospitals.[12]

Birthweight outcomes for births in Mexico City and for Mexican Americans from southwestern states were compared through the use of various birthweight measures (medians, percentage under 1500 g, percentage under 2500 g) and by graphing altitude-specific birthweight distributions for the two groups. Graphs of the various birthweight distributions were produced using the SAS/GRAPH package.[13] The curves were based on 500-g intervals, smoothed using cubic spline interpolation.

Results

A comparison of birthweights in the two groups without adjustment for altitude shows a sharply higher low birthweight rate in Mexico City, almost double the Mexican-American rate, and a differ-

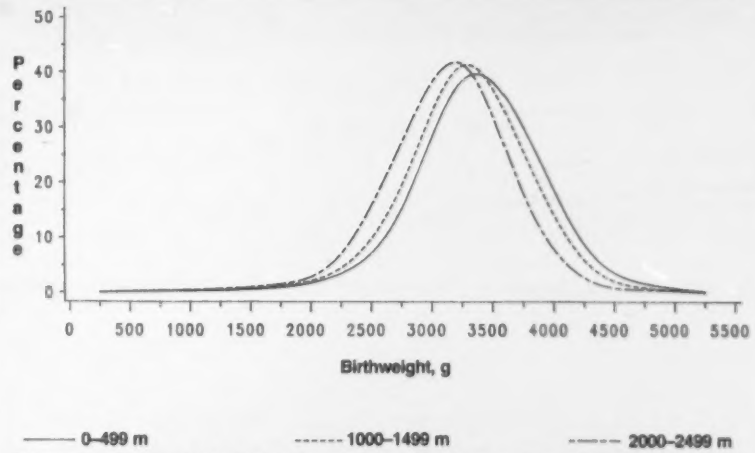

FIGURE 2—Birthweight distributions by altitude: US Southwest Mexican Americans, 1980 to 1984. Sources: US National Center for Health Statistics, national vital statistics data, 1980 to 1984, and Bureau of Health Professions, Area Resources File, 1980.

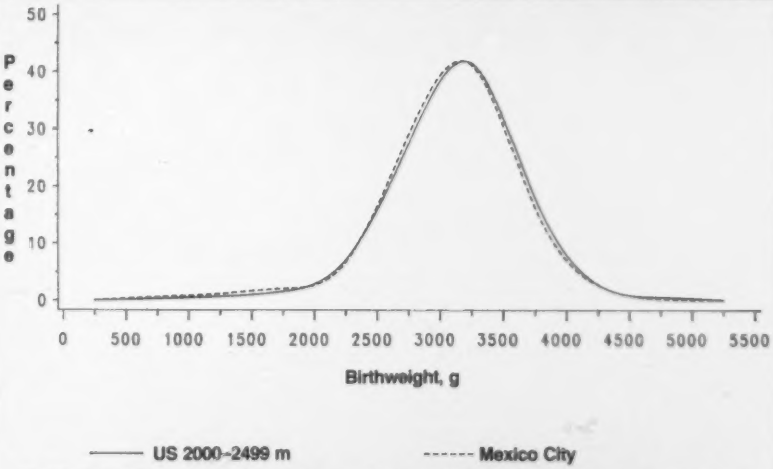

FIGURE 3—Birthweight distributions, adjusted for altitude: US Southwest Mexican Americans, 1980 to 1984, and Mexico City Residents, 1984. ence in median birthweights of almost 275 g (Table 2). Comparing the percentage distributions of birthweights in the two populations shows that strong differences exist throughout the range of birthweights (Figure 1).

Differences in altitude have been shown to have a strong impact on birthweights for US Whites.[14,15] Altitude is thought to retard fetal growth because of the lower oxygen content of air at higher elevations, resulting in fetal hypoxia. The result is to increase not only the proportion of births below 2500 g, but to reduce birthweights throughout the distribution.

Figure 2 provides strong evidence that Mexican-American birthweight also is affected by altitude. As shown in the figure, the Mexican-American distribution shifts leftward with each increase in altitude. Figure 3 compares the Mexico City distribution with the Mexican-American curve for the most similar altitude, that is, for births to mothers residing at 2000 to 2499 m. The two curves are quite similar, and for births weighing more than 2500 g they virtually overlay. Differences remain for low birthweights, but much reduced from the curves presented in Figure 1.

Table 3 shows that the association between altitude and birthweight is present even at relatively low levels of elevation, as median birthweights drop consistently with each 500-m increment in altitude (χ^2 test for trend, $P < .001$). This table also shows that by controlling for altitude, the difference in low birthweight rates has been sharply reduced, so that the Mexico City rate is less than 10% greater than the Mexican-American rate at the same altitude (10.6% vs 9.7%, respectively). In addition, the difference in median birthweight has been reduced from 274 g to 47 g.

An alternative explanation for the association between altitude and birthweight is that altitude and socioeconomic status could be negatively correlated in the United States, so that poorer Mexican Americans would tend to live at higher altitudes. However, controlling for maternal education, as a proxy for socioeconomic status, has little effect on either the Mexico City/Mexican-American comparison or on the strength or consistency of the effect of altitude on birthweight (data not shown).

Discussion

The results presented in Figure 2 and Table 2 provide compelling evidence of the strength of the effect of altitude on birthweight. An increase in altitude of as little as 500 m affects not only the proportion of births under 2500 g, but causes the entire birthweight distribution to shift leftward. An increase of 2000 m almost doubles the percentage of low birthweight among Mexican Americans (from 5.5% to 9.7%), while the median birthweight declines by 227 g (3374 g to 3147 g). These results illustrate how misleading low birthweight rates, unadjusted for altitude, can be as indicators of health status or of general economic development.

The larger proportion of births under 2500 g in Mexico City, as compared with those of Mexican Americans, underlines the greater problem with pathological conditions in the Federal District, and presumably elsewhere in Mexico. A part of this excess however, may be due to the overrepresentation of tertiary-level hospitals, and thus of high-risk deliveries, in the Mexico City study. In addition, some differences in nutritional status remain between the two groups: maternal weight is almost 9 kg lower for Mexico City mothers (53.5 kg and 62.4 kg, respectively), and there is a 5-cm difference in their average

height (152.9 cm for Mexico City mothers vs 157.7 cm for Mexican Americans).[16,17]

By demonstrating the similarity in birthweight distributions between the Mexico City population and Mexican Americans, once altitude has been taken into account, these results help to confirm the validity of Mexican-American birthweight data. In addition, they suggest that adverse living conditions are not major determinants of birthweight in either of the two populations. The results also support previous research indicating that the lifestyle of Mexican-American women provides protection against the effect of adverse socioeconomic conditions on birthweight, including low smoking rates and the presence of social networks.[18] In addition, Mexican Americans have a higher maternal ponderal index and a lower proportion of primiparous births as compared with White non-Hispanics, which can also improve the birthweight distribution.[19] Further clarification of this "public health enigma" will require additional research. □

Identification of Nonfatal Family and Intimate Assault Incidents in Police Data

Linda E. Saltzman, PhD, James A. Mercy, PhD, and Philip H. Rhodes, MS

ABSTRACT

We examined different strategies for identifying nonfatal family and intimate assaults (FIAs) in police data. Police most often classify such incidents in the "assault" category, but they also use other crime categories. We estimated that, during 1984, 3300 FIAs (or 837 per 100 000 population) occurred in Atlanta. Of those, 77% were classified as assaults; 23% were classified in nonassault categories. Research measuring the magnitude of FIAs should take into account incidents classified in nonassault crime categories. (*Am J Public Health.* 1992;82:1018–1020)

Introduction

Police data are a systematic, ongoing collection of information about crime and a valuable resource in examining the epidemiological patterns and causes of violence among intimates.[1,2] Police data on family and intimate assaults (FIAs) can benefit communities in several ways: a minimum FIA rate can be estimated; groups at high risk of FIA involvement can be identified to target prevention strategies; and the data can be used to help evaluate intervention strategy effectiveness.

We describe how one city's police incident reports were sampled to estimate the number of nonfatal FIAs in a year, and how different strategies for identifying FIA incidents affect rate estimates.

Methods

As part of a larger study,[3] we reviewed nonfatal incident reports for 1984 from the Bureau of Police Services in Atlanta, Ga. FIAs met four criteria: (1) incident reports described one or more of the following circumstances: physical contact between parties, use of a weapon, threat with a weapon, or verbal threat of bodily harm; (2) the incident had occurred in the city of Atlanta and within Fulton County; (3) the victim's residence was Atlanta within Fulton County; and (4) the victim and perpetrator were emotionally intimate at the time of the incident or before it occurred.

Threats and physical contact causing no discernible injuries were included as FIAs because they often escalate to violence with serious injury or homicide.[4] We required both incident location and victim's residence to be within Atlanta and Fulton County because (1) such victims were eligible for county agency services and the larger study required records reviews at public agencies; and (2) population estimates were available for that defined geographic area, enabling calculation of FIA rates.

Incidents were eligible for classification as FIAs if the perpetrator-to-victim relationship was included among a list of relationships implying closeness or emotional intimacy (e.g., a married couple). The list included familial relationships, former relationships, and relationships without legal definition (e.g., a cohabiting or dating couple). For incidents with multiple perpetrators, at least one perpetrator's relationship to the victim had to be emotionally intimate. Incident reports without relationship information (nearly 25% of reports reviewed) were considered ineligible.

Atlanta police incident reports are filed within Federal Bureau of Investigation (FBI) Uniform Crime Report[5] (UCR) categories. In keeping with the UCR's crime hierarchy, assaults that occur during incidents of homicide, rape, and robbery are classified in those "higher-order" crime categories and not as assaults. Thus, reviewing cases from the assault crime category automatically misses some incidents involving assault. Similarly, several "lower-order" categories include incidents meeting our case definition.

Because the proportion of FIAs classified in any of these nonassault crime categories was unknown, we did a pilot review. We took a simple random sample of 1984 incident reports in each of seven nonfatal FBI crime categories. The sample sizes in the strata ranged from 1% (assault, a large category with 10 560 incident reports) to 15% (family and children offenses, a small category with only 192 incident reports). The pilot sample provided a working guess as to the relative number of records contributed by each of the seven crime categories. This initial assessment was done to establish guidelines for selecting the actual study sample, not to provide final estimates of the numbers of FIAs.

The authors are with the Centers for Disease Control's National Center for Environmental Health and Injury Control in Atlanta, GA.

Requests for reprints should be sent to Linda E. Saltzman, Centers for Disease Control, 1600 Clifton Road, MS-F-36, Atlanta, GA 30333.

This paper was submitted to the Journal March 6, 1991, and accepted with revisions October 18, 1991.

Using the pilot results, we then set target numbers for FIAs within each strata (total n across all strata = 150). Within each crime category, we randomly selected and reviewed records until we obtained the target number of FIAs (i.e., negative binomial sampling). We reviewed a total of 945 incident reports in the seven nonfatal crime categories (519 classified as assault and 426 incident reports classified in the other six categories) to obtain 150 cases satisfying the case definition for FIA. Case distribution reflected the estimated percent of nonfatal FIAs in 1984 contributed by each crime classification: rape (n = 2); robbery (n = 3); assault (n = 125); disorderly conduct (n = 13); family and children offense (n = 2); sex offense (n = 1); and other (n = 4).

To estimate FIA incidence, we multiplied the known number of incident reports in each of the seven nonfatal crime categories by the estimated proportion of records within each crime category meeting the FIA case definition. The total estimated number of FIAs is the sum of the estimates for the seven crime categories. The incidence estimates were then used to calculate 1984 nonfatal FIA victimization rates for (1) incidents classified in all seven nonfatal crime categories, (2) incidents classified only in the assault crime category, and (3) incidents classified as nonassault crimes. Population estimates for the city of Atlanta within Fulton County came from the Atlanta Regional Commission's 1985 population update,[6] because complete population data were not available for 1984.

Approximate 95% confidence intervals (CI) for the numbers and rates per 100 000 population were calculated based on the actual sampling design, but other calculations indicated that an assumption of simple stratified random sampling within each crime category would have given almost identical results. Confidence interval calculations are based on an assumption of a normal distribution. The distribution of the log (number of events) meets this assumption better than the distribution of the number of events. Therefore, the confidence intervals are not symmetric around the point estimates because they were initially calculated around the log (number of events) and then converted back to the original scale. Within each crime category, the probabilities are closer to 0 than to .5 that any particular police incident report meets the FIA case definition. Thus, the confidence intervals extend slightly higher above the point estimates than below them.

TABLE 1—Incidence Estimates, Nonfatal Family and Intimate Assaults (FIAs), Atlanta, Georgia, 1984

Incident Report Classification	Number of Incident Reports	Estimated FIAs (95% CI)	Percent of Total FIAs	Percent FIAs in Crime Category
Assault	10 560	2541 (2175, 2959)	77	24
Nonassault Crime[a]	12 996	759 (513, 1112)	23	6
Total	23 556	3300 (2846, 3821)	100	14

[a] Nonassault crime classifications include rape, robbery, disorderly conduct, family and children offense, sex offense, and other.

Results

We estimated that 3300 (14%) of the 23 556 incident reports filed in the seven crime categories in Atlanta in 1984 were FIAs (Table 1). Of the 10 560 incidents classified as assault, we estimated that 24% were FIAs; and of the 12 996 incident reports in the other six categories, we estimated that 6% were FIAs. Of the estimated 3300 FIAs, 77% were contributed by incidents from the assault category and 23% were contributed by incidents from the combined nonassault crime categories.

The FIA rate based on all seven nonfatal crime categories was 837 per 100 000 population (95% CI = 724–967). The FIA rate based only on incidents classified as assault was 645 per 100 000 population (95% CI = 552–749).

Discussion

Although we estimated that 77% of FIA incidents in Atlanta in 1984 were classified as crimes of assault, the number of FIAs classified as nonassault crimes was not negligible. Our finding that some FIA incidents were classified in higher-order UCR crime categories (rape, robbery) is consistent with analysis of National Crime Survey data; of reported violent incidents among intimates, 89% involved the crime of assault, 9% involved robbery, and 2% involved rape.[7]

The 30% increase in the FIA victimization rate when nonassault-classified FIAs are combined with assault-classified FIAs suggests that analyses using police data should either include nonassault-classified FIAs or acknowledge the likelihood that estimates solely from assault-classified FIAs are underestimates. Much intimate violence never comes to the attention of the police,[8,9] so even with the addition of nonassault-classified FIAs, police data will underestimate FIA incidence and victimization rates. For many communities, however, police data provide the *only* routinely collected information about FIAs. Furthermore, the police are often the first to contact assault participants, and police can provide information about those encounters that is unavailable from other sources.

Because UCR data collection has not routinely included information about the perpetrator-to-victim relationship for nonfatal incidents, it was not surprising that nearly a fourth of the incident reports we reviewed lacked such information. Imminent changes occurring with the FBI's National Incident-Based Reporting System (NIBRS) should greatly improve the utility of police data for studying FIAs because NIBRS will routinely include perpetrator-to-victim relationship information for nonfatal crimes.[10]

Communities wishing to establish FIA surveillance might consider the following recommendations.

1. Determine what police data on FIA are already available in the community, and explore the feasibility of undertaking new or expanded data collection. In particular, consider expanding routinely recorded information to include the perpetrator-to-victim relationship.

2. In large jurisdictions, sample police incident report records, recognizing that the resources needed to collect information on all FIA incidents would be great. Smaller jurisdictions may be able to collect information about all incidents more easily.

3. Incorporate not only incidents classified in additional nonfatal crime cat-

egories besides assault but also homicide incidents.

4. Use any resulting data to modify or initiate community policies that address prevention of family violence and other assaults among intimates. It will help if efforts can be made to establish (or strengthen) communication links between criminal justice and public health agencies, and between those agencies and community advocacy groups concerned about FIA. □

Acknowledgments

This paper uses data from the study of Family and Intimate Assaults in Atlanta (FINAA), supported under a collaborative agreement (#U50/CCU400931-01-1) between the Centers for Disease Control and the Georgia Department of Human Resources, with the additional collaboration of the Fulton County (Georgia) Health Department and the Atlanta Department of Public Safety.* Additional support was provided through an interagency agreement (#86-IJ-R-200) with the National Institute of Justice.

The Cost and Frequency of Hospitalization for Fall-Related Injuries in Older Adults

Bruce H. Alexander, MS, Frederick P. Rivara, MD, MPH, and Marsha E. Wolf, PhD

ABSTRACT

Using a population-based hospital discharge registry with E codes, we examine the 1989 hospitalizations of older adults in Washington State for fall-related injuries. Fall-related trauma accounted for 5.3% of all hospitalizations of older adults, with hospital charges totaling $53 346 191, and resulted in discharge to nursing care more often than other such hospitalizations. An annual hospitalization rate of 13.5 per 1000 persons and an annual cost of $92 per person is reported. The importance of preventing fall-related injuries in older adults is discussed. (*Am J Public Health*. 1992;82:1020–1023)

Introduction

The risk of falls and of fall-related injury increases with age owing to loss of agility and visual acuity, predisposition to dizziness and syncope, and side effects from medications.[1–7] Approximately 30% of older adults will experience a fall annually, and 20% to 30% of those people will suffer moderate to severe injuries[6,8] leading to loss of mobility and independence and to an increased risk of death.[1,2,9–11] A growing body of literature is available on risk factors for fall-related injuries, especially fracture of the hip, and has been reviewed by others elsewhere.[1,2,5] However, complete data on these injuries in a population, along with attendant cost and morbidity information, have not been well presented. To characterize the frequency and cost of fall-related injuries that result in hospitalization, a population-based study was conducted of all persons aged 65 years and older in Washington State who were hospitalized in 1989 after a fall.

Methods

Hospital discharge data were obtained from the 1989 Washington State

Commission Hospital Abstract Reporting System, which collects discharge data from all Washington State hospitals, excluding Veterans Administration and military hospitals.

Patients were initially divided into the following six mutually exclusive categories, based on *International Classification of Diseases* (*ICD*) discharge codes and E codes indicating, respectively, presence or absence of trauma and the external cause of injury.

1. *Fall-related trauma: ICD* trauma code (800–904, 910–957) and an E code for a fall (E880–E889).

2. *Nonfall-related trauma: ICD* trauma code and an E code for trauma excluding falls and intentional injury (E800–E848, E890–E899, E916–E928).

3. *Trauma of unknown cause: ICD* trauma code but no E code recorded.

4. *Noninjury hospitalizations:* All *ICD* discharge codes lower than 800.

5. *Nontrauma injuries: ICD* code for late effects from external cause (905–909) or late effects of trauma, poisonings, or medical misadventure (958–998); and an E code for poisoning (E850–E869), medical misadventure (E870–E876), environmental effects (E900–E909), suffocation or submersion (E910–E915), late effects of injury (E929), adverse effects of medication (E930–E949), or intentional injury (E950–E999).

6. *Nontrauma injuries, unknown cause: ICD* codes 905–909, 958–998 but no E code recorded. Groups 4, 5, and 6 were ultimately combined to form an "all nontrauma" category. Population-based rates were calculated using age- and sex-specific denominator data for Washington in 1989 based on projections from 1980 and 1990 census data.[12]

The frequency of hospitalizations in each discharge category for persons over age 65 in Washington State in 1989 was broken down by age, gender, source of admission, and discharge status; and age- and sex-specific hospitalization rates for falls, other trauma, and nontrauma among this population were calculated. The cost of fall-related injuries was based on hospital charges only, exclusive of professional fees.

Results

Of the 149 504 patients aged 65 years and older who were discharged from Washington State hospitals in 1989, 7873 (5.3%) were hospitalized for injuries from falls (Table 1). Compared with persons hospitalized for other reasons, persons admitted for falls were more frequently female and tended to be older.

Patients hospitalized for fall-related trauma were discharged to a nursing facility more often than were those hospitalized for other reasons (Table 1). This finding was independent of age and patient status prior to admission. Patients admitted from home with fall-related injuries were discharged to a nursing facility more often than were patients hospitalized both for other trauma combined and for reasons not related to trauma (42% vs 23% and 14%, respectively) (Table 2).

The rate of hospitalization for fall-related trauma, 13.5 per 1000 persons aged 65 and older, was five times that of nonfall-related trauma (Table 3). The rate for falls increased with age and was higher among women than among men.

Of the $995 499 233 in hospital charges in 1989 for persons in Washington State aged 65 and older, $53 346 191 (5.3%) were attributable to hospitalization of patients with fall-related trauma. The annual per capita cost of such hospitalizations was higher for women and increased remarkably with age (Table 4).

Discussion

Population-based hospital discharge data with E codes were used to describe

TABLE 2—Age-Adjusted Distribution of Discharge Destinations for Patients Admitted from Self Care

Destination upon Discharge	Trauma[a] Fall Related (n = 7485) %	Trauma[a] Nonfall Related (n = 1296) %	Trauma[a] Unknown Cause (n = 2180) %	Nontrauma[b] (n = 137 903) %

Total	114	62	92

the frequency and cost of hospitalization for fall-related injuries in the older adult population of Washington State. These data confirm other research that implicates falls as the leading cause of injury in the aged.[2,5,13,14] The rates of such injuries in Washington were similar to national estimates reported by Rice et al.[13]

Fall-related injuries profoundly affect the activity and life-style of older adults. Forty-three percent of patients injured in falls were discharged to a nursing facility, a figure similar to that reported by Sattin et al.[15] Noninstitutionalized persons injured in falls were discharged to nursing care three times more often than were persons hospitalized for nontrauma causes.

Hospital costs for fall-related injuries in older adults is one of the more striking findings of this analysis. However, these hospitalized fall injuries account for only a fraction of the total cost.[13] Among an elderly population in Florida, only 42% of those who sought medical attention for a fall were hospitalized.[15] And the more than $53 million spent in hospital costs do not take into account the long-term sequelae of fall-related injuries, which include loss of independence, loss of confidence, susceptibility to future falls, and poor survivorship.[9,10] Clearly, the entire cost of falls among older adults in Washington State, whether measured in monetary or in human terms, is much greater than $92 per person per year (Table 4).

The Washington State Commission data have limitations typical of hospital discharge registries. Because the five discharge diagnosis codes are not prioritized, some falls may be secondary to comorbid conditions. Furthermore, E coding, though mandated by law, is not 100% complete; consequently, some of the injuries with unknown cause in fact may have been incurred by falls. Finally, no information is available regarding the course of the patient once discharged.

Although the etiology of falls is complex, fall injury research has identified several potentially modifiable risk factors[1–3,6,7,16] and fall prevention strategies.[5] Faulty vision, improper footwear, and common household hazards such as loose rugs are examples of previously identified risk factors. Currently unproven but potentially effective one-time interventions to reduce these risks deserve further attention. The cost-effectiveness of such interventions will increase over time as the risk and annual per capita cost of falls in older adults increase with age. These interventions may not prevent all falls, but

they could reduce the effect of falls on the older adult population. □

Carcinogens in Tobacco Smoke: Benzo[a]pyrene from Canadian Cigarettes and Cigarette Tobacco

Murray J. Kaiserman, PhD, and William S. Rickert, PhD

ABSTRACT

We evaluated the benzo[a]pyrene (BaP) content in the smoke from 35 brands of Canadian cigarettes and 5 brands of Canadian tobaccos for roll-your-own cigarettes. For the cigarettes, mean values of BaP ranged from 3.36 ng to 28.39 ng per cigarette, roughly in proportion with declared tar values. The relationship between declared tar and yields of BaP, however, does not allow accurate prediction of one from the other. For the tobaccos, mean BaP values ranged from 22.92 ng to 26.27 ng (average, 24.7 ng) per cigarette. The implications of these findings are discussed with respect to overall exposure. (*Am J Public Health.* 1992;82:1023–1026)

Introduction

The particulate fraction of tobacco smoke ("tar") is composed of a complex mixture of constituents,[1,2] some of which are regulated under environmental legislation.[3–6] One constituent is benzo[a]pyrene (BaP), a polynuclear aromatic hydrocarbon formed during the incomplete combustion of organic matter such as gasoline, garbage, and plants. BaP has been identified by the International Agency for Research on Cancer as an animal carcinogen and a probable human carcinogen (Class 2A)[7] with inhalation, oral ingestion, and dermal absorption as the important routes of entry.

Human data are unavailable, but oral ingestion of about 7 to 9 mg of BaP per kilogram has produced cancers in laboratory animals.[8] With respect to tobacco smoke, BaP has been detected in concentrations ranging from 20 to 40 ng per cigarette in mainstream cigarette smoke[1] to 40 to 79 ng per cigarette in sidestream smoke[1] and 96 to 292 ng per cigar in mainstream cigar smoke.[9]

On January 1, 1989, the Tobacco Products Control Act came into force in Canada. One of the purposes of this legislation is to "enhance public awareness of the hazards of tobacco use by ensuring the effective communication of pertinent information to consumers of tobacco products."[10] To achieve this goal, the Health Protection Branch of Health and Welfare Canada has undertaken a series of studies to develop and validate analytical test methods for toxic constituents.

In this paper we report on the BaP delivery of 35 brands of commercially available Canadian cigarettes and 5 brands

of commercially available Canadian fine-cut tobaccos for making roll-your-own cigarettes.

Methods

Smoking Procedures and Sample Collection

The 35 brands of cigarettes and 5 brands of fine-cut tobaccos were collected at the retail level in March and April of 1989 in Montreal and Vancouver. Brands were chosen to include some of the most popular brands in the market, including Players Light Regular Size (12.9% market share), Export A Regular Size (5.7% market share), and Rothmans King Size (3.7% market share).[11] The preparation of roll-your-own cigarettes and the smoking conditions for all cigarettes are described elsewhere.[12]

BaP was collected and analyzed according to the method described by Tomkins et al.[13] In this procedure, ^{14}C-labeled BaP is added to each sample and values, as determined by high-pressure liquid chromatography (HPLC), are corrected for ^{14}C recovery.

Recovery Study

Five Canadian control cigarettes (Monitor 4) were smoked per port on 10 randomly selected ports of a 20-port smoking machine and the mainstream particulate fraction was collected on a Cambridge filter pad, providing a total of 10 samples.

During cleanup, 100 µl of tracer solution was added to six of these samples at six different steps before HPLC isolation and 25 µl of tracer solution was added to two of the samples at two different steps after isolation and before HPLC quantitation. To determine 100% recovery, two of the samples were left unspiked (no tracer solution added) until just prior to injection onto the HPLC analytical column.

Validation Study

Five Kentucky Reference 2R1 cigarettes were smoked per port on 10 randomly selected ports of a 20-port smoking machine and the mainstream tar was collected on a Cambridge filter pad, resulting in another 10 samples. All samples were spiked with 100 µl of the tracer solution. Five of the pads were further spiked with 107.6 ng of unlabeled BaP. The workup then proceeded as described by Tomkins et al.[13]

Results and Discussion

Recovery and Validation Studies

The recovery and validation studies provide a measure of the precision, accuracy, and efficiency of the methods used. Observed recovery rates of BaP were 100% ± 8%. During the course of the experiment, the average recovery rate was 89% for the control cigarettes and 91% for fine-cut tobacco cigarettes; these rates were in good agreement with published results of 85% BaP recovery.[13] The results of the validation study provided a value of 31.9 ± 3.7 ng per cigarette for the unspiked 2R1 cigarette; this value was in good agreement with published values of 32 ng per cigarette[9] and 28.4 ± 3.4 ng per cigarette.[13]

Cigarette and Fine-Cut Tobacco Studies

Table 1 shows declared pack values for tar, nicotine, and carbon monoxide, and values for BaP as determined in this study. The results for BaP are averages of five observations per brand (25 cigarettes). (Although the current practice is to report yields on a per-cigarette basis, it should be pointed out that five cigarettes are required for each analytical value and the per-cigarette yield is obtained by division.)

Mean values for BaP range from 3.36 ng per cigarette to 28.39 ng per cigarette and are linearly related to declared tar values (correlation coefficient of 0.89 for all samples). Because the reported values reflect smoke concentrations under standard conditions, the smoker of low-yield cigarettes is probably exposed to higher amounts than those reported in Table 1.

Figure 1 shows the results of a regression analysis of mean BaP on declared tar. Although the simple linear correlation coefficient is fairly high at .89, the points are widely dispersed about the regression line, resulting in broad 95% confidence limits for the regression line. This means, for example, that at 16 mg declared tar, the BaP level is predicted to lie between 15 and 28 ng per cigarette. Thus, although

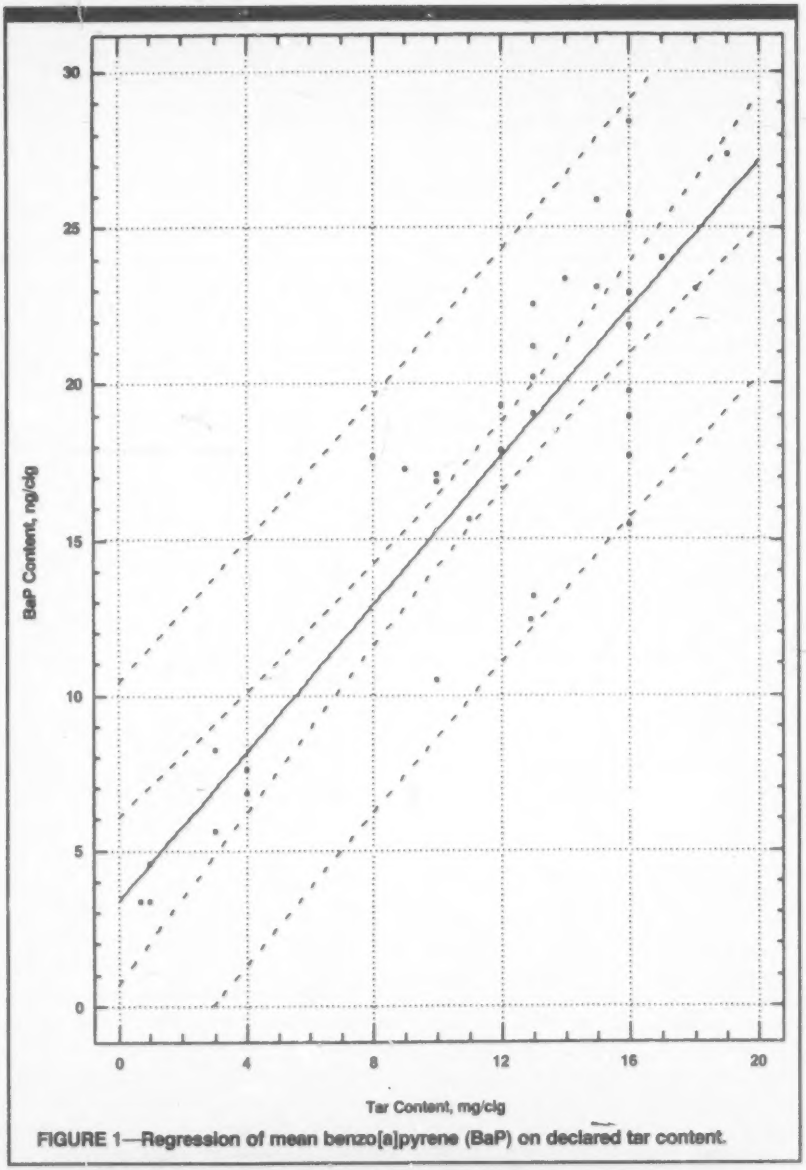

FIGURE 1—Regression of mean benzo[a]pyrene (BaP) on declared tar content.

TABLE 2—Mean Benzo[a]pyrene (BaP) and Declared Tar, Nicotine, and Carbon Monoxide (CO) Concentrations per Cigarette for Cigarettes Prepared from Five Brands of Roll-Your-Own Tobacco

Brand	Tar, mg	Nicotine, mg	CO, mg	BaP, ng
Players	23	1.8	19	25.02
Export	17	1.5	17	25.93
Craven A	19	1.5	19	23.34
Rothmans	19	1.5	19	26.27
Number 7	19	1.5	19	22.92

BaP is linearly related to declared tar, declared tar is not a good predictor of BaP.

Table 2 shows declared tar, nicotine, and carbon monoxide values and mean analytical BaP values for the five brands of fine-cut tobaccos used in preparation of roll-your-own cigarettes. Once again, BaP yields are averages of five observations per brand. These values range from 22.92 to 26.27 ng per cigarette; the average value was 24.7 ng per cigarette.

The Occupational Safety and Health Administration (OSHA) in the United States has set advisory levels for BaP of 0.2 $\mu g/m^3$ (8-hour time-weighted average permissible exposure limit for occupational exposure).[5] Assuming average breathing rates of 0.63 m^3/hour (women) to 1.08 m^3/hour (men) for alternating periods of light work and rest,[14] the permitted maximum amount of inhaled BaP in an occupational environment would be from 1.01 μg in 8 hours to 1.73 μg in 8 hours. A pack-a-day smoker who consumed 20 cigarettes in 8 hours could be expected to inhale from 0.067 μg to 0.568 μg from this source. Although the actual amount would vary depending upon individual smoking behavior, it is obvious that, for smokers, cigarette smoke is a significant source of exposure to BaP, contributing as much as one third the daily permitted exposure recommended by OSHA.

To clarify the risk further, the state of California mandates a "no significant risk" level for BaP of 0.06 μg per day.[6] A pack-a-day smoker (20 cigarettes) will inhale between one and ten times this level. For smokers, current advisory levels should be modified to take into account the contribution from tobacco smoke.

Although BaP is just one of 60 to 70 known toxic constituents of tobacco smoke,[1,2,7] many smokers continue to believe that tar is the most significant toxic constituent of tobacco smoke and that cigarettes with reduced tar are safer.[1,15] One reason for this misconception may be lack of knowledge of the components of tobacco smoke in a familiar context. □

Discrepancies between Self-reported Smoking and Carboxyhemoglobin: An Analysis of the Second National Health and Nutrition Survey

Lisa M. Klesges, MS, Robert C. Klesges, PhD, and Jeffrey A. Cigrang, MS

ABSTRACT

Environmental, self-report, and demographic factors mediated the relationship between self-reported cigarette smoking and carboxyhemoglobin among 2114 smokers and 3918 nonsmokers. Self-reported nonsmokers with carboxyhemoglobin levels between 2% and 3% were more likely to be self-reported ex-smokers, to live in a larger community, and to be younger, less educated, and male than were self-reported nonsmokers with carboxyhemoglobin levels of less than 2%. Self-reported nonsmokers with strong evidence of cigarette consumption (carboxyhemoglobin level > 3%) were more likely to be self-reported ex-smokers, younger, less educated, and non-White than were nonsmokers with carboxyhemoglobin levels of less than 2%. (*Am J Public Health.* 1992;82:1026–1029)

Introduction

Because of uncertainties inherent in measurement of smoking behavior using self-report,[1] biochemical measures are frequently used to validate reported smoking exposure. Although cotinine is often the preferred biochemical measure of smoking exposure,[2] blood carbon monoxide concentration is useful in many circumstances. It is less expensive to measure and can discriminate smokeless tobacco products from cigarette, pipe, and cigar smoking. It can also verify smoking cessation in treatment programs using nicotine replacement. Carbon monoxide is particularly useful in establishing health risks of smoking because of its strong relationship with cardiovascular disease.[3]

The current study sought to investigate factors associated with discrepancies between self-reported smoking status and carboxyhemoglobin levels. By identifying circumstances under which carboxyhemoglobin levels and self-reported smoking status do not agree, investigators can make more informed judgments about the validity of these measures of smoking and the associations between smoking and morbidity when carboxyhemoglobin is used.

Methods

The study sample consisted of 6032 participants from the Second National Health and Nutrition Examination Survey (NHANES II), aged 18 to 74 years, who completed a carboxyhemoglobin assessment. Detailed description of the survey methodology for NHANES II is available.[4] Self-reported smoking status was ascertained by asking participants whether they currently smoked cigarettes, how many they smoked on average, and whether they smoked cigars or pipes. Subjects reporting no current use of tobacco products were considered nonsmokers, while those smoking pipes or cigars were excluded. Carboxyhemoglobin concentrations, determined by spectrographic assay,[5] are expressed as percentages of total hemoglobin combined with carbon monoxide. Statistical analyses were performed using the Statistical Analysis System.[6] Collinearity diagnostics, as discussed by Hosmer and Lemeshow,[7] did not reveal unreliable estimates.

Results

Table 1 provides a demographic description of the study sample. Although the distributions overlapped, the average carboxyhemoglobin level of smokers was higher than that of nonsmokers. Based on its discriminant ability in previous investigations,[8,9] a carboxyhemoglobin level of 2% or more was used to identify smokers. Table 2 shows the relationship between self-reported smoking and elevated carboxyhemoglobin levels. Using carboxyhemoglobin as the standard, sensitivity and specificity were 84.8% and 95.8%, respectively, while the positive predictive value of carboxyhemoglobin was 91.5%. Two thirds of discrepancies involved subjects who reported that they smoked but had carboxyhemoglobin levels of less than 2%.

Subjects who reported smoking but had carboxyhemoglobin levels of less than 2% were categorized on cigarette rate (i.e., <10 cigarettes per day or 10+ cigarettes per day). Logistic regression equations compared each of these subgroups with self-reported smokers having carboxyhemoglobin levels of 2% or more. The first analysis compared the low cigarette consumption group with the accordant carboxyhemoglobin group. The odds of misclassification (see Table 3) were higher for Whites and those with lower cigarette consumption. Subjects who had carboxyhemoglobin levels of less than 2% and smoked 10+ cigarettes per day were also compared with smokers with accordant carboxyhemoglobin levels (≥2%). The odds of having discrepant vs accordant carboxyhemoglobin levels were increased for Whites, men, and those with lower cigarette consumption and higher body mass.

Among self-reported nonsmokers, logistic regression analyses were performed to identify factors that discriminated discrepant vs accordant subjects. Because marginally elevated carboxyhemoglobin levels may result from passive exposure and large elevations are more likely due to cigarette exposure, two logistic regression analyses were conducted. In the first, predictors of accordance (i.e., carboxyhemoglobin level < 2%) vs marginal discrepancies (i.e., carboxyhemoglobin level between 2% and 3%) were evaluated. In the second analysis, predictors of accordance vs severe discrepancies (i.e., carboxyhemoglobin level > 3%) were assessed.

Predictors of marginal discrepancies are presented in Table 4. Male subjects were more likely to be misclassified as smokers (61% more at risk) than were female subjects. Also, misclassification decreased with advancing age and education. The strongest predictor was size of the community of residence. The odds of having marginally discrepant carboxyhemoglobin levels increased threefold from rural to large urban (>3 million) areas. Finally, self-reported ex-smokers were 55% more likely to have discrepant carboxyhemoglobin levels than were never smokers.

The second logistic regression compared self-reported nonsmokers with carboxyhemoglobin levels of more than 3% and those with carboxyhemoglobin levels of less than 2%. Those with strong evidence of cigarette consumption were 75% more likely to be reported ex-smokers and twice as likely to be non-White compared with accordant nonsmokers. As age and education increased, the odds of having discrepant vs accordant carboxyhemoglobin levels decreased.

Self-reported nonsmokers	3752 (95.8)	166 (4.2)
Self-reported smokers	321 (15.2)	1793 (84.8)

Discussion

The agreement between self-reported smoking and carboxyhemoglobin level of 91.9% is consistent with previous studies not using bogus pipeline or pipeline procedures to increase the validity of self-reports.[9,10] Discrepancies between self-reports and carboxyhemoglobin levels were not random but were predicted by demographic and smoking-related variables. The conundrum of these discrepancies is to differentiate falsification of self-reported smoking from failure of carboxyhemoglobin measures.

Because of this uncertainty, the role of biochemical verification in general surveys of smoking behavior remains controversial. Some data suggest increasing falsification in general surveys,[11,12] while other studies conclude that self-reports are superior to biochemical measures.[13] Self-reports of smoking in cessation pro-

grams are inaccurate[14,15] as a result of interest in pleasing experimenters, experimental demand, and social pressures against smoking. Although falsification is reduced by bogus pipeline procedures[16] (i.e., subjects believe their reports will be biochemically validated), actual biochemical verifications are often recommended. Since, as the current findings suggest, carboxyhemoglobin level failed to predict the smoking status of certain individuals, blanket recommendations for carboxyhemoglobin verification are premature until the sources of disagreements between self-reports and carboxyhemoglobin levels are better understood. At present, the need for verification should be based on the characteristics of the target sample or cohort and the circumstances surrounding the collection of data.

Disagreement was highest (15.2%) in subjects who reported that they smoked but had carboxyhemoglobin levels of less than 2%. Discrepancies were predicted by the dosing variables of cigarettes per day and body mass, as well as race and sex. Because unmeasured smoking topography may differ by race and sex, it is difficult to distinguish physiological differences in carbon monoxide absorption and elimination from carbon monoxide exposure variables. However, regardless of causative factors, using carboxyhemoglobin level as the sole criterion of smoking for these individuals would bias estimates of disease risk related to smoking and the efficacy of treatment programs. Self-reports for these individuals are preferred over carboxyhemoglobin levels alone because the failure of carboxyhemoglobin is greater than that of self-reports in establishing smoking.

Self-reported nonsmokers with carboxyhemoglobin levels greater than 3% are most likely misreporting smoking because large elevations in carboxyhemoglobin levels attributed to carbon monoxide emissions are uncommon.[17] Self-reported exsmokers were likely to misreport smoking status, perhaps because of the social pressures of participating in a health examination survey. They may intend to quit smoking or have relapsed recently and want to claim ex-smoking status. Likewise, younger, non-White, and less-educated subjects misreported at a higher rate than their respective counterparts. These individuals may be responsive to perceived demand by interviewers or reticent to report smoking habits. Inhalation of carbon monoxide from other organic substances or occupational sources may be responsible for some carboxyhemoglobin elevations. Carbon monoxide in marijuana smoke reportedly increases false-positives.[18]

Finally, that marginal elevations in carboxyhemoglobin levels among self-reported nonsmokers may be due to passive exposure to carbon monoxide is supported by the finding that size of community predicted these marginal elevations. Marginal elevations were also predicted by being non-White and poorer educated, which may, in part, be explained by carbon monoxide emission in the home environment and occupational exposures[17] or a higher incidence of hemolytic anemia[19] in these individuals. □

Recall of AIDS Public Service Announcements and Their Impact on the Ranking of AIDS as a National Problem

Michael Siska, MS, Janine Jason, MD, Paul Murdoch, MBA, Wen Shan Yang, PhD, and Robert J. Donovan, PhD

ABSTRACT

The efficacy of two public service announcements from Phase V of the "America Responds to AIDS" (ARTA) campaign was assessed at two sites. Participants were randomly assigned to view a local news program, one with an ARTA public service announcement appearing six times and the other with no AIDS public service announcements. During telephone interviews with 907 participants 1 to 3 nights after viewing, 21% at Site A and 59% at Site B could correctly recall the ARTA public service announcements. Absolute mentions of AIDS as an important national issue increased. (*Am J Public Health.* 1992;82:1029–1032)

Introduction

The evaluation of finished public health media material is often recommended for public health campaigns.[1–3] In late May and early June of 1990, the National AIDS Information and Education Program of the Centers for Disease Control ran a field study to test the short-term efficacy of two television public service announcements regarding human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) from Phase V of the "America Responds to AIDS" (ARTA) campaign. The two public service announcements were "Wonderful World," which shows children playing in a field and a little girl talking about wanting to grow up in a better world, and "Sofa," which shows a young couple on a sofa kissing while an an-

nouncer on the television in front of them talks about AIDS.

The study addressed four questions: (1) Did either public service announcement increase awareness of AIDS as an important national issue? (2) Did people remember the announcements? (3) Was one more effective than the other in accomplishing these two objectives? (4) Did either produce negative effects?

Methods

Each public service announcement was tested at a discrete site: "Wonderful World" was randomly assigned to the Springfield, Ill, "area of dominant influence," as defined by Arbitron, Inc,[4] and "Sofa" was randomly assigned to the Memphis, Tenn, area of dominant influence. A week prior to the study, 4181 eligible households were contacted via a random-digit dialing system. Of those contacted, 1909 (46%) declined to participate, 341 (8%) did not receive the channel they were asked to watch, and 1931 (46%) agreed to participate. An even gender distribution of participants 18 to 54 years old was randomly assigned to the exposed or unexposed (control) groups. Of the 1931 respondents agreeing to participate, 907 (47%) completed the follow-up questionnaire (Table 1).

At recruitment, participants were told only that the study was to examine important health and national issues facing the nation; AIDS was not mentioned. They were asked to watch one of two local late news programs and then asked to list "the most important problems facing our country today." The question on important health and national issues was also the first question asked during the follow-up interview to avoid any bias in responses. One station in each city aired no AIDS public service announcements (the control station). One station in each city was paid to air the announcement two times per night for 3 consecutive nights on its 10:00 PM news program, and each agreed to air no other AIDS public service announcements. The news programs were scheduled to air simultaneously, from 10:00 PM to 10:30 PM from May 29, 1990, through May 31, 1990, but the actual timing of the news programs and public service announcement airings was changed because of the National Basketball Association playoffs (Figure 1). After the scheduling problem was discovered, attempts were made to contact all of the study participants and ask for their continued cooperation. Follow-up telephone interviews were completed from June 1, 1990, through June 3, 1990.

TABLE 3—Demographic Characteristics of Study Participants by Exposure Category, Memphis

Demographic Category	Exposed, % (No.) (n = 211)	Control, % (No.) (n = 243)
Gender		
Male	45 (94)	47 (113)
Female	55 (117)	53 (130)
Age		
18–24	9.5 (20)	14 (34)
25–34	33 (70)	30 (73)
35–44	39 (82)	33 (81)
45–54	18.5 (39)	23 (55)
Ethnic group		
White	65 (137)	63 (151)
Black	34 (72)	36 (88)
Other	1 (2)	1 (3)
Marital status		
Married	63 (134)	65 (158)
Never married	25 (52)	21 (50)
Divorced/separated/widowed	12 (25)	14 (35)
Education		
Less than high school	9 (19)	11 (26)
High school graduate	23 (49)	27 (67)
Some college	39 (82)	35 (84)
College graduate	20 (43)	15 (37)
Postgraduate education	9 (18)	12 (29)
Income		
< $15 000	18 (36)	19 (45)
$15 000–$35 000	44 (90)	37 (87)

TABLE 4—Proportion of Exposed Participants Recalling an AIDS Message, by Study Site

	Study Site, No. (%)	
	Springfield (n = 230)	Memphis (n = 211)
Unprompted	66 (24.4)	90 (42.7)
Prompted	47 (20.4)	63 (29.9)
Total	113 (44.8)	153 (72.6)

Note. Unprompted recall represents those respondents who replied by describing an AIDS message when asked if they had seen any public health messages. Prompted recall represents those who responded positively to the prompt "Did you see any commercial messages or public health messages that dealt with AIDS?" if they had not mentioned an AIDS message when asked if they had seen a public health message.

Results

The demographic characteristics of exposed vs control participants at both sites are presented in Tables 2 and 3.

The proportion of exposed participants recalling "an AIDS message" was significantly higher in the Tennessee site than in the Illinois site (Table 4; $P < .001$). In addition, 59% of those in Tennessee assigned to the exposure group could correctly recall specific elements of the "Sofa" public service announcement; 21% of those in Illinois assigned to the exposure group could correctly recall specific elements of "Wonderful World" ($P < .001$).

The proportion of participants mentioning AIDS as an important issue increased at both sites from recruitment to follow-up for the exposed groups, but not for the unexposed groups (Table 5). Mentions of AIDS increased 54.8% in Memphis (20.8% to 32.2%) and 72.9% in Springfield (9.6% to 16.6%). Categories of exposed participants vs unexposed participants were based strictly on recruitment assignment.

Three open-ended items were used to examine whether the public service announcements had unintended negative effects. In Illinois, 5 of 453 responses to an AIDS prevention question referred to "quarantine" of infected persons, 2 in the exposed group and 3 in the unexposed group. In Tennessee, 1 of 211 exposed respondents described the public service announcement as "offensive" and 1 described it as "too passionate to be shown on television." Since the general viewing population also could view the public service announcement, the station airing the announcement in Tennessee was questioned about complaints. The station received only 5 complaints, a number it classifies as negligible compared with a strong reaction, which it classifies as 25 or more calls and/or letters.

Discussion

A number of real-world problems and limitations were encountered in this study. First, unexpected scheduling changes occurred during the study. Second, all exposure information was self-reported. The validity of self-reported measures has been questioned,[5] but this method was the only practical one in this situation. Third, the overall response rate was low (47%), possibly because of the relatively large effort required of participants and the unforeseen scheduling changes. However, response rates to telephone surveys have been declining in recent years as a result of the proliferation of telephone survey research and telemarketing attempting to disguise itself as research.[6,7]

Day-after recall of an advertisement for a given product averages 20% (range = 0% to 70%).[8] Thus, the recall levels of "Wonderful World" (21%) and "Sofa" (59%) are comparable or superior to the recall levels obtained in commercial advertising.

The mention of AIDS as an important issue by exposed participants also increased at both sites. Baseline levels did differ between sites, and differed between groups in Springfield. Also, participants in Memphis may have been sensitized by an AIDS special that ran on a local news program 1 week prior to the study, which may account for baseline differences between sites. However, no stories on AIDS appeared on any of the news programs over the 3 nights. The public service announcements were the only AIDS-related materials aired. Furthermore, the increases were significant and occurred only among the exposed participants.

"Sofa" appeared more effective than "Wonderful World" in terms of viewer recall. Both appeared effective in prompting viewers to cite AIDS as an important issue facing the nation. However, direct

TABLE 5—Proportion and Change in Proportion Mentioning AIDS as an Issue, by Exposure Category

Category	Participants Mentioning AIDS, % Pre	Post	Change, %	P
Springfield				
Exposure	9.6	16.6	+ 7.00	.03
Control	17.5	17.5	...	NS
Memphis				
Exposure	20.8	32.2	+11.4	.01
Control	14.8	16.5	+ 1.6	NS

Note. At recruitment, and again during the follow-up interview, respondents were asked simply, "In your opinion, what are the most important problems facing our country today?" Up to the first five answers were recorded.

comparisons of the public service announcements are confounded by study site and airing schedule differences. It should also be noted that these results cannot be generalized to the entire viewing population.

Despite problems and limited exposure, this study shows that under field conditions viewers do recall ARTA public service announcements, and these announcements can affect viewers' beliefs concerning AIDS as a national problem. Furthermore, neither public service announcement produced negative effects.

The testing of finished public health media material is beneficial for practical decision making. For example, prior to this study, the Tennessee Department of Health had concerns that Tennessee residents would find the "Sofa" public service announcement offensive. However, the study results did not indicate this to be the case, and the announcement was later aired on a statewide basis.

Since ARTA campaign materials include print, radio, and television public service announcements and informational brochures and these materials are distributed extensively, and because this trial involved only six exposures over a short period of time, effects on attitudes and behaviors were not expected. However, future efficacy studies will be adapted to test for these effects. Upcoming efficacy studies will be run in several markets for 12 to 20 weeks following the release of the materials. They will examine various broadcast media combinations and media emphasis in relation to campaign objectives. □

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc, 1015 Fifteenth St, NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50 000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health,* 1015 Fifteenth St, NW, Washington, DC 20005.

Information on Manuscript Preparation is published monthly in the Journal. The Journal publishes reports of original research, research methods, program evaluations, analytic reviews, including health policy analysis, and reports for special departments. A paper is considered with the understanding that it or its essential substance neither has been published nor is under consideration elsewhere.

Subscription price, individual, is $100/year US, $140/year international; **institutional,** $160/year US, $200/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to *American Journal of Public Health,* 1015 Fifteenth St, NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Schultz, Advertising Manager, APHA, 1015 Fifteenth St, NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Pregnancy-Related Mortality in New Jersey, 1975 to 1989

Kristen J. Mertz, MD, MPH, Artist L. Parker, MD, MPH, and George J. Halpin, MD, MPH

ABSTRACT

Objectives. National data are thought to underestimate pregnancy-related mortality in the United States. A multisource surveillance system for pregnancy-associated deaths in New Jersey offers an opportunity to identify the magnitude of and the trends in pregnancy-related mortality at the state level.

Methods. Data from all reported pregnancy-related deaths in the state from 1975 to 1989 were studied, and pregnancy mortality ratios were calculated.

Results. The New Jersey pregnancy mortality ratio decreased from the late 1970s to the early 1980s but began to rise in the late 1980s. The pregnancy mortality ratio for non-Whites was 3.6 times that for Whites for the 15-year period. The causes of pregnancy-related deaths changed over the 15-year period, with direct obstetrical causes playing a decreasing role. AIDS has become the major cause of pregnancy-related mortality in New Jersey. Finally, approximately 44% of the pregnancy-related deaths were considered to be preventable by the physician or patient or both.

Conclusions. New efforts must be made to combat the recent rise in pregnancy-related deaths, with special attention to preventing deaths among non-White women. (*Am J Public Health.* 1992;82:1085–1088)

Introduction

In studying deaths of pregnant and postpartum women, one statistical measure used by the Centers for Disease Control (CDC) is the pregnancy mortality ratio, the number of pregnancy-related deaths per 100 000 live births.[1] Pregnancy-related deaths include both direct deaths (which result from complications of pregnancy, labor, or delivery) and indirect deaths (which result from preexisting medical conditions that are exacerbated by pregnancy). Nonmaternal deaths, not included in the pregnancy mortality ratio, involve pregnant or postpartum women who die of causes unrelated to pregnancy (e.g., injuries, homicides) within the specified time frame. "Pregnancy-associated deaths" is an all-encompassing term that includes direct, indirect, and nonmaternal deaths.

Progress in preventing pregnancy-related deaths in recent decades has been impressive. National vital statistics data compiled by the National Center for Health Statistics (NCHS) show a decline in the pregnancy mortality ratio from 376 per 100 000 live births in 1940[2] to 7.8 per 100 000 in 1985.[3]

Despite this progress, pregnancy-related mortality remains a significant public health issue for several reasons. There is reliable evidence that national vital statistics data based solely on death certificates understate pregnancy mortality rates when compared with rates measured by data systems that supplement vital records with other forms of surveillance.[1,4,5] In addition, national rates are low only for Whites, with non-White rates being three times higher.[3,6] Furthermore, upon review, one third to one half of pregnancy-related deaths are considered preventable.[7,8,9] Finally, deaths from AIDS have begun to increase the pregnancy mortality ratio in some areas.[10]

Instituted in 1974, multisource surveillance and review of pregnancy-related deaths in New Jersey provide an opportunity to more accurately estimate the magnitude and trends in pregnancy-related mortality.[11] Death certificates, maternity service reports, physicians, other hospital personnel, medical examiners, and, more recently, computer searches of death tapes and hospital discharge tapes are all sources for the identification of pregnancy-associated deaths, which are reportable by law to the New Jersey Department of Health. The New Jersey Medical Society's Subcommittee on Maternal Mortality has collaborated with the New Jersey Department of Health since 1974 in an annual review of all cases.

Methods

The New Jersey Department of Health maintains confidential case files—which include death certificates, hospital records, prenatal charts, and autopsy reports—on all women who died while pregnant or within 42 days postpartum. We compiled a database that included variables on demographic information, pregnancy history, social history, delivery, and fetal outcome. Cause of death, classification (direct, indirect, or nonma-

This paper was submitted to the Journal April 18, 1991, and accepted with revisions April 7, 1992.

TABLE 1—New Jersey Pregnancy Mortality Ratios, 1975 to 1989

	Whites Ratio (No.)	Non-Whites Ratio (No.)	Total Ratio[a] (No.)[b]
Five-year period of death			
1975–1979	15.3 (55)	62.1 (60)	24.7 (115)
1980–1984	12.7 (48)	29.8 (31)	16.1 (79)
1985–1989	11.9 (51)	52.4 (64)	20.3 (115)
Age group			
≤19	12.1 (11)	31.2 (24)	21.4 (35)
20–24	11.4 (32)	31.9 (32)	18.3 (64)
25–29	11.6 (49)	50.0 (40)	17.9 (89)
30–34	12.6 (35)	77.2 (36)	22.5 (71)
35–39	18.7 (15)	92.8 (15)	35.8 (30)
≥40	108.0 (12)	286.0 (8)	153.0 (20)

Note. The pregnancy mortality ratios were calculated from data collected on the whole population or entire subpopulations of New Jersey, not on a sample of the population, and thus confidence intervals are not necessary.
[a]Number of pregnancy-related deaths per 100 000 live births. The number of live births includes multiple births and omits miscarriages, fetal deaths, and stillbirths.
[b]Number of pregnancy-related deaths.

ternal), and preventability had been determined by consensus of the Maternal Mortality Subcommittee of the New Jersey Medical Society, and these variables were added to the database.

Pregnancy mortality ratios were calculated by year, race, age, county, insurance status, cause of death, and preventability. The denominator data (numbers of live births by year, race, age, and county) were provided by the New Jersey Department of Health's Center for Health Statistics.[12] Hispanic live births were grouped with Whites until 1989 and thus pregnancy mortality ratios could only be calculated for Whites and Hispanics combined (Whites) and for non-Hispanic Blacks, Asians, Native Americans, and all other races combined (non-Whites). The data on number of live births by insurance status for the years 1985 to 1988 were provided by the New Jersey Department of Health's Division of Health Planning and Resource Development.

Results

Of the 404 pregnancy-associated deaths reviewed by the New Jersey Medical Society, seven were not classified and 88 were classified as nonmaternal and will not be considered here. The remaining 309 pregnancy-related deaths give an overall pregnancy mortality ratio of 20.3 deaths per 100 000 live births in New Jersey for the years 1975 to 1989. The general trend in the ratio in New Jersey was downward until it began to increase after 1985, rising to a high of 33.2 in 1988. The 5-year pregnancy mortality ratio varied from 24.7 for 1975 to 1979, 16.1 for 1980 to 1984, and 20.3 for 1985 to 1989 (Table 1).

Demographic Differences

The total 15-year pregnancy mortality ratio for non-Whites was 48.0 per 100 000 live births, 3.6 times as high as the ratio for Whites (13.2 per 100 000). After a substantial decrease between the periods 1975 to 1979 and 1980 to 1985 (62.1 to 29.8), the pregnancy mortality ratio for non-Whites increased to 52.4 in 1985 to 1989, whereas the ratio for Whites continued to decline from 15.3 to 12.7 to 11.9 over the same time periods (Table 1). The non-White to White ratio of race-specific pregnancy mortality ratios changed from 4.1 for 1975 to 1979 to 2.3 for 1980 to 1984 and 4.4 for 1985 to 1989.

The pregnancy mortality ratios by age group show that the pregnancy mortality risk in New Jersey during 1975 to 1989 was far higher for women aged 40 or older (Table 1). Women aged 20 to 24 and 25 to 29 had the lowest pregnancy mortality ratios (18.3 and 17.9, respectively). Within each age group the ratio for non-Whites was higher than that for Whites.

The pregnancy mortality ratios varied considerably by county, with the highest ratios in urban counties with large non-White populations. Essex County had the highest ratio, with 38.3 pregnancy-related deaths per 100 000 live births, followed by Hudson, Mercer, and Union Counties at 31.9, 26.4, and 25.5, respectively. The county-specific pregnancy mortality ratios were correlated with county-specific non-White population percentages (Pearson correlation coefficient = .84). In 15 of the 21 counties, the pregnancy mortality ratio for non-Whites was higher than the ratio for Whites. The remaining six counties have small non-White populations and had pregnancy mortality ratios of zero for non-Whites.

Pregnancy mortality ratios by insurance coverage could only be calculated for 1985 to 1988 because denominator data were available for only these years. Of the 97 pregnancy-related deaths that occurred during these 4 years, insurance status was recorded for 74 (73%) of them. These 74 accounted for pregnancy mortality ratios of 10.8 for those women with private insurance, 34.3 for women covered by Medicaid, and 32.7 for self-pay patients. Insurance status for live births was not available by race, so pregnancy mortality ratios by both payer and race could not be calculated.

Cause of Death

The underlying cause of death was obtained from the death certificate and presumably reflected findings on autopsy, performed in about 71% of the cases. The leading causes of pregnancy-related mortality in New Jersey changed significantly over the course of the three time periods. The cause-specific pregnancy mortality ratios for hypertension in pregnancy, thromboembolism, hemorrhage, and stroke (the leading causes of death in 1975 to 1979) all decreased in the 1980s (Table 2). The pregnancy mortality ratio for AIDS increased from 0.0 before 1985 to 2.3 per 100 000 in 1985 to 1989, the highest cause-specific ratio of that period. Other indirect causes also played an increasing role in 1985 to 1989. From 1975 to 1989, the cause-specific pregnancy mortality ratios were higher for non-Whites than Whites for every major cause of death (Table 2).

Preventability

The New Jersey Medical Society's Subcommittee on Maternal Mortality assigned preventability status to all but 7% of the pregnancy-related deaths for 1975 to 1989. Of those categorized, 56% were considered to be nonpreventable, 34% were considered to be preventable by physician factors, 5% preventable by patient factors, and 5% preventable by both patient and physician factors. Thus, for all deaths for which preventability status was assigned, 44% were considered preventable by the physician or patient or both.

The pregnancy mortality ratio for preventable deaths with a component of physician responsibility decreased from

the first time period to the second but showed no further decrease in the third (ratios of 9.5, 6.3, and 6.4, respectively) (Table 3). However, for non-Whites the pregnancy mortality ratio for physician-preventable deaths increased in the second half of the 1980s, paralleling the increase in pregnancy-related deaths as a whole for that period. For the total 15-year period, the pregnancy mortality ratio for physician-preventable deaths was 4.8 times as high for non-Whites as it was for Whites (19.5 per 100 000 compared with 4.1 per 100 000).

Discussion

Several findings in this study are of particular interest. First, we found that pregnancy mortality ratios for New Jersey are higher than the national ratios described by the NCHS, the CDC, and the Maternal Mortality Collaborative.[3,5,6,13,14] However, a comparison of New Jersey and national data may be misleading because of different systems of surveillance and different definitions of pregnancy-related mortality. Surveillance with death certificates alone leads to underestimation of pregnancy-related mortality [4,5,11,15] New Jersey's multiple-source surveillance system allows the state to identify pregnancy-related deaths that might not be identified by the NCHS and the CDC in other jurisdictions.

On the other hand, New Jersey uses a 42-day postpartum period in its definition, whereas the Maternal Mortality Collaborative and the CDC use a one-year postpartum period. Of the deaths reported to the Maternal Mortality Collaborative, 11% of postpartum deaths took place after 42 days postpartum.[5] Thus New Jersey data may underestimate the number of pregnancy-related deaths when compared with the Maternal Mortality Collaborative and the CDC. A uniform methodology for identifying, defining, and classifying pregnancy-associated deaths will have to be developed for use throughout the country before meaningful comparisons can be made.

The second issue of concern is the exceptionally high pregnancy mortality ratio for non-Whites in New Jersey (48.0/100 000). This ratio far exceeds the US Public Health Service's health objective for 1990 of a maternal death rate of less than 5 per 100 000 for any ethnic group in the United States.[16] Of particular concern is the high rate of physician-preventable deaths for non-White women as compared with that for White women, which suggests a possible discrepancy in the quality of obstetrical care provided to Whites and non-Whites. Special efforts must be made to improve obstetrical care, access to prenatal care, and family planning services in order to reduce the number of pregnancy-related deaths among non-White women.

Also of concern are the high pregnancy mortality ratios for women on Medicaid or without any health insurance coverage. The pregnancy mortality ratios by payer calculated for 1985 to 1988 underestimate the true ratios for this period because of the exclusion of several pregnancy-related deaths for which insurance status was not known. In addition, we could not analyze the payer data by race. The interaction between race, health insurance status, and poverty should be studied in greater detail in an attempt to separate individual effects.

The data also show that indirect causes of pregnancy-related death, such as AIDS, are replacing direct obstetrical causes in New Jersey. This trend has implications for the practice of obstetrics and the design of regional perinatal systems. Perinatal providers must now involve other medical personnel, such as infectious disease specialists, in the management of pregnancy in order to reduce mortality from indirect causes such as AIDS. Toward this end, perinatal systems will have to include a wider base of consultants to care for pregnant women with underlying disease. In addition, obstetricians and other health providers, through preconception counseling, must emphasize the danger of pregnancy when a significant underlying disease exists and help provide access to contraceptive services. □

The Roseto Effect: A 50-Year Comparison of Mortality Rates

ABSTRACT

Objectives. Earlier studies found striking differences in mortality from myocardial infarction between Roseto, a homogeneous Italian-American community in Pennsylvania, and other nearby towns between 1955 and 1965. These differences disappeared as Roseto became more "Americanized" in the 1960s. The present study extended the comparison over a longer period of time to test the hypothesis that the findings from this period were not due to random fluctuations in small communities.

Methods. We examined death certificates for Roseto and Bangor from 1935 to 1985. Age-standardized death rates and mortality ratios were computed for each decade.

Results. Rosetans had a lower mortality rate from myocardial infarction over the course of the first 30 years, but it rose to the level of Bangor's following a period of erosion of traditionally cohesive family and community relationships. This mortality-rate increase involved mainly younger Rosetan men and elderly women.

Conclusions. The data confirmed the existence of consistent mortality differences between Roseto and Bangor during a time when there were many indicators of greater social solidarity and homogeneity in Roseto. (*Am J Public Health.* 1992; 82:1089–1092)

Introduction

Previous studies of social correlates of health and longevity have focused mainly on ethnic, occupational, or demographic characteristics rather than on the social character and group dynamics of an identified community. An exception is the study of Roseto, Pennsylvania, an Italian-American town in eastern Pennsylvania that from 1955 to 1965 was found to have had a strikingly low mortality rate from myocardial infarction relative to Bangor, an immediately adjacent town, and three other nearby communities.[1,2] The usually accepted risk factors were at least as prevalent in Roseto as in the two control communities that were studied in detail.[3,4] At the time, Roseto, which had been settled by immigrants from a town in southern Italy in 1882, still displayed a high level of ethnic and social homogeneity, close family ties, and cohesive community relationships.

Beginning in 1962, Roseto became the object of detailed inquiries into its history and social traditions and the attitudes, behavior, health habits, and medical status of its residents. For comparison, the adjacent community of Bangor (which, throughout what became a 50-year period under study, was served by the same water supply, physicians, and hospital facilities as Roseto) and the nearby town of Nazareth were studied in similar fashion. Data from these studies and many years of participant observation yielded evidence that the discrepancy in the prevalence of and mortality from myocardial infarction might be attributed to important differences in culture and social cohesion among the three communities.[1–5] It was hypothesized that Roseto's stable structure, its emphasis on family cohesion, and the supportive nature of the community may have been protective against heart attacks and conducive to longevity. However, by the early 1960s there were indications of impending change in the community.[5] Interviews with many Rosetans between the ages of 25 and 35 and with the teenagers indicated that they were prepared to largely abandon their old community ways in favor of the more typically American behavior of neighboring communities.

In 1963, after the initial period of study, the investigators made a prediction that the loosening of family ties and community cohesion would be accompanied by loss of relative protection of Rosetans from death due to myocardial infarction.[4] By the late 1960s and early 1970s the predicted social change was evident, as was the predicted increase in incidence of myocardial infarction. These changes were reflected in greater prevalence of myocardial infarction among the living and in higher mortality rates.[2,13,14]

The earlier beliefs and behavior that expressed themselves in Roseto's family-centered social life, absence of ostentation even among the wealthy, nearly exclusive patronage of local business, and a predominance of intra-ethnic marriages gradually changed toward the more familiar behavior pattern of neighboring commu-

Roseto women	193.0	46	159.5	50	125.1	51	150.0	75	93.9	70

nities. Roseto was shifting from its initially highly homogeneous social order—made up of three-generation households with strong commitments to religion and to traditional values and practices—to a less cohesive, materialistic, more "Americanized" community in which three-generation households were uncommon and inter-ethnic marriages became the norm.[15]

The "Roseto Effect" has been widely cited as evidence for the positive effects of social cohesion and social support on longevity.[6–12] In order to reexamine the possibility of bias in the mortality data due to the small population size of Roseto (approximately 1600 during the time of the study, with the Bangor population numbering more than 5000), and to test the possibility that the relative differences in mortality rates from one decade to another were due to random fluctuations in the number of deaths in each town, we examined 3859 death certificates from Roseto and Bangor from 1935 to 1985.

Method

With the help of the Bureau of Vital Statistics in the Pennsylvania Department of Health, we were able to obtain and individually examine all death certificates of inhabitants of Roseto and Bangor who died between 1935 and 1985. Because pre-1960 certificates had to be retrieved manually, we were concerned about the completeness of our data. We therefore examined all obituary notices in the local newspaper as well as church death records for the entire time period of this study; we were thus able to identify and obtain the records of residents whose certificates had not been filed or retrieved appropriately. Obituaries and church records also made it possible to identify and obtain the death certificates for Roseto and Bangor residents who had died while they were traveling outside of Pennsylvania.

Diagnostic Criteria

The criteria for the diagnosis of death from myocardial infarction included all instances when myocardial infarction was listed on line one of the death certificate as "immediate cause of death" or when "sudden death" was listed in that space and myocardial infarction, ischemic heart disease, arteriosclerotic cardiovascular disease, coronary heart disease, or similar phrases were used in the "due to" lines.

Criteria for the diagnosis of congestive heart failure included the listing of congestive heart failure, chronic ischemic heart disease, chronic myocarditis, cardiomyopathy, and similar phrases as immediate cause of death, accompanying the listing of atherosclerosis or arteriosclerosis as a contributing cause.

Age Adjustment and Standardization

Mortality rates in the two towns were standardized for age, using as the standard population the sum in each age group in Roseto and Bangor in 1940. Rates were computed for deaths from myocardial infarction, congestive heart failure, and all causes. The ratio of Roseto to Bangor rates was then calculated, and statistical significance was assigned to differences at the 95% confidence level.[16]

Since the focus of our interest was coronary disease, age-adjusted death rates were computed only for those aged 35 and older. Rates were based on 10-year averages over the period 1935 to 1985, using the 5 years on either side of an official census count, with the census figures as the denominator. Although the age composition of the two populations changed dramatically over time, standardization of the rates takes this into account. (See the Appendix for complete census data.)

Results

Table 1 presents age-adjusted mortality rates from myocardial infarction, congestive heart failure, the two combined, and for all causes for the two communities over the course of five decades. The mortality rate for myocardial infarction among Roseto men and women was initially very low but showed a progres-

*Significant at confidence levels of 95%; under 1.0 the Roseto rate is lower.

sive rise over the 30-year period from 1935 to 1964. The rate for men in Bangor also rose during this time, while rates for Bangor women peaked in the period from 1955 to 1964. In the decade 1965 to 1974 there was a sharp increase in mortality from myocardial infarction among Roseto men and women. For women, the increase from the 1955 to 1964 decade was entirely in the 65 and older population, but for men it occurred in every age group and most dramatically in all 10-year age groups younger than 65 (see Table 2). In contrast, rates for congestive heart failure generally declined over the course of the five decades. Total mortality rates declined in both communities, although the drop is considerably greater for women than for men.

Table 3 shows the Roseto to Bangor ratios and confidence intervals of mortality rates for total deaths and for myocardial infarction, congestive heart failure, and the two combined. The results indicate that the rates of death from all causes for men are significantly lower in Roseto for all decades except 1965 to 1974. For women they are significantly lower in 1955 to 1964 and 1975 to 1984 but significantly higher from 1965 to 1974.

Although there were no significant differences between the two communities in congestive heart failure until the last decade, the mortality rates for myocardial infarction in both men and women in Roseto were significantly lower than those for Bangor men and women over the initial period of thirty years. After 1965 this difference disappeared. When myocardial infarction and congestive heart failure are combined, Roseto men had a mortality advantage over Bangor men from 1935 until 1965.

Discussion and Conclusion

After a very thorough search of all sources of data for mortality in two small Pennsylvania communities over the course of 50 years, our examination of death certificates has confirmed the earlier inference, based on a shorter span of years, that the death rate from myocardial infarction was lower in Roseto than in immediately adjacent Bangor in three decades prior to 1965. The difference between the two communities is statistically significant despite the small number of myocardial infarctions. The sharp rise that followed involved mainly young Rosetan men and elderly women at a time when the predicted decrease in social cohesion became clearly manifest, as described in detail elsewhere.[14,15] The increase in myocardial in-

farction in Roseto was accompanied by a similar increase in total mortality.

This remarkable pattern suggests systematic differences between the two neighboring communities over the course of at least 30 years—years for which there are many indicators of greater social solidarity and homogeneity in Roseto and no evidence of differences in coronary risk factors.[15] The social changes that occurred in Roseto in the 1960s are reflected in sharply increased rates of heart attack among men under the age of 65. □

The Quality of Life in the Year before Death

ABSTRACT

Objectives. Most Americans wish to live a long healthy life, but fear disease and dependency in their last years. Until recently, little has been known about the prevalence of opposite extremes of health in old age, particularly in the period leading up to death.

Methods. We used results from the 1986 National Mortality Followback Survey to estimate proportions of elderly decedents who were "fully functional" or "severely restricted" in the last year of life. Estimates were based on responses from proxies to questions regarding the decedent's functional status, mental awareness, and time spent in institutions.

Results. Approximately 14% of all decedents aged 65 years and older were defined as fully functional in the last year of life; 10% were defined as severely restricted. Proportions varied with the decedent's age and sex, the underlying cause of death, and the presence of other preexisting conditions.

Conclusions. Results from this survey and future surveys can be used to learn more about "successful agers"—their medical histories, their life-styles, and whether their relative number is increasing or decreasing over time. (*Am J Public Health.* 1992; 82:1093–1098)

Introduction

Americans born in the late 1980s could expect to live into their 70s, and those reaching their 65th birthday at that same time could expect to live almost two additional decades.[1] With the expectation of long life after age 65 has come the desire for accompanying good health, and, correspondingly, the fear of spending one's final years in a state of severe disability and dependency. As was noted in the now decade-old *Healthy People: the Surgeon General's Report on Health Promotion and Disease Prevention,* "older Americans hope for a state of well-being which would allow them to perform at their highest functional capacity. . . . Their greatest fear is of being useless, sick or unable to care for themselves."[2]

Until recently, little has been known about the distribution of functionality in populations of older persons. Several recent studies have looked at predictors of health status among samples of the elderly[3–8]; however, none of these efforts has focused on the period preceding death. This period is important, in part, because those who live long lives and are vibrant until shortly before death may provide the best possible example of "successful aging."[9]

In this study, we developed a simple multidimensional index to estimate extremes in health status in the last 12 months of life among a nationally representative sample of persons who died in 1986. We also examined several demographic, health, and social factors to identify important correlates of being fully functional or, conversely, severely disabled in these final months.

Methods

National Mortality Followback Survey Sample

For this analysis, we extracted all deaths of individuals aged 65 years and older from the 1986 National Mortality Followback Survey (NMFS) (n = 7586). The NMFS is a stratified random sample of approximately 1% of all deaths among US residents (excluding residents of Oregon, who were not sampled) aged 25 years and older that occurred in 1986 (n = 18 733).[10] This survey, conducted by the National Center for Health Statistics, collected detailed information on health status and health care provided in the last year of life and on aspects of lifestyle that are potential risk factors for disease and disability. Most information was collected from proxy respondents by mail questionnaire, by telephone, or by personal interview. Information on the underlying cause of death and all associated causes came from the official death certificate. Because information for comorbid conditions (conditions that occurred or were prevalent at least 12 months before death and were not

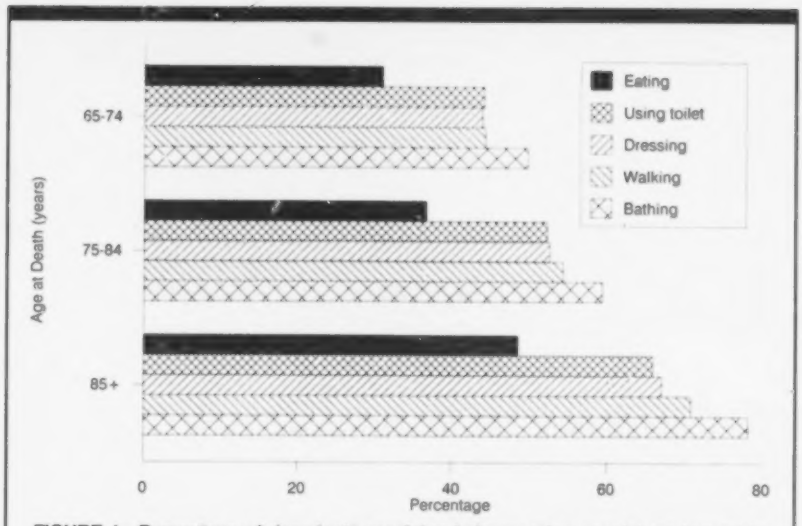

FIGURE 1—Percentage of decedents receiving help or using special equipment to perform activities of daily living in last year of life, by age at death.

the underlying cause of death) was unavailable for a number of decedents, we had a reduced sample (n = 5582) for this portion of the study. However, the characteristics of this subsample closely matched those of the full sample.

Creation of an Index

We examined a subset of responses to questions asked on the NMFS. Proxy respondents were asked if the decedent had "received help or used special equipment" in the last year of life in five separate activities of daily living (ADLs)—eating, using the toilet, dressing, walking, and bathing—and if so, over what period of time. They were asked how often in that same period the decedent had trouble understanding where he or she was, remembering what year it was, or recognizing family or good friends. The respondent was also asked how many nights the decedent spent in hospitals and nursing homes in the last year of life.

Results from all three sets of questions were used to construct a simple additive index of health, and two groups of decedents with opposite profiles were identified. We defined as "fully functional" those who during the last year of life needed no assistance or special equipment to carry out the five basic ADLs listed above, who were lucid until the last few hours or days before death, and who spent less than a week in a hospital or nursing home. At the other extreme were "severely restricted" individuals, who needed help or special equipment for 6 months or more in at least three of five ADLs and more limited assistance in the remaining two, who exhibited at least some decline in mental functioning, and who spent at least half of their last year in a hospital or nursing home.

Statistical Methods

The number and proportion of decedents who were fully functional in their last year and of those who were severely restricted were estimated for three age groups: 65 to 74 years, 75 to 84 years, and 85 years and older. Variances and confidence intervals were computed by using generalized parameters provided by the National Center for Health Statistics.[11]

We used separate logistic regression models to estimate the likelihood of being fully functional or severely restricted in the last year. Decedents who fit these definitions were compared with all other decedents; that is, the fully functional were compared with all decedents experiencing greater restrictions, and the severely restricted were compared with all decedents experiencing fewer restrictions.

We calculated regression coefficients, odds ratios, and variances by using the raw sample reweighted to account for the stratified sampling design but not for the effects of clustering. For both sets of models, the odds ratios reflect the relative likelihood of being fully functional or severely restricted, adjusted for single year of age, and in the presence of other important factors.

Results

Characteristics of the Respondents

The relationship of the respondents to the deceased varied according to the characteristics of the decedent. Although a member of the immediate family was most often the proxy respondent, other relatives, friends, and acquaintances were more likely to be proxies for female than for male decedents (24% vs 15%), for Black than for White decedents (25% vs 19%), and for those who died at age 85 years or older (27%) than for those who died at ages 75 to 84 years (20%) or 65 to 74 years (12%).

Components of the Index

The proportion of respondents requiring assistance with ADLs rose with age at death (Figure 1). For all age groups, decedents were least likely to need help eating and most likely to need help bathing.

Among those who died between the ages of 65 and 74, roughly 15% had had trouble knowing where they were, 13% remembering the year, and about 10% recognizing family or good friends (Figure 2). These proportions increased with age; the oldest decedents were more than twice as likely as the youngest to have cognitive limitations.

Of those who died between the ages of 65 and 74, 7.2% spent more than half of their last year in a nursing home. Among those who died between the ages of 75 and 84, the corresponding figure was 17.4%. But of those who died at the age of 85 years or older, 39.3% spent at least half of their last year in a health care facility.

Health Status and Demographic Characteristics

Approximately 14% of all decedents who died at age 65 years and older were defined as fully functional in the last 12 months of life. A slightly lower proportion, 10%, met our definition of severely restricted. As might be expected, the proportion of decedents at the definitional extremes varied with age in very different ways. One fifth of those who died between the ages of 65 and 74 met our definition of fully functional in the last 12 months, but the percentage dropped to 6% among the oldest group; by contrast, only 3% of the youngest group but 22% of those aged 85 years and older were severely restricted.

Differences by sex were pronounced. A smaller proportion of women than men were fully functional in the last 12 months

of their lives, and a larger proportion were severely restricted. This was true for decedents in all three age groups (Figure 3). For the oldest decedents, the differences are substantial: roughly 10% of the men vs 4% of the women remained unrestricted in the last year, whereas 13% of the men vs 26% of the women met the definition of severely restricted.

We also examined health status by race and marital status at death. We found few significant differences and noted no consistent pattern across marital status subgroups. Of those who died before the age of 85, Whites appeared more likely than Blacks to be either fully functional or severely restricted, although the differences were not always statistically significant.

Health Status and Cause of Death

In general, a higher proportion of those who died of acute myocardial infarction (AMI) were fully functional, and a lower proportion were severely restricted, than were those who died of other causes (other forms of heart disease, cancer, cerebrovascular disease and all other causes) (Table 1). In contrast, fewer than 1 in 20 persons who died of cancer could be defined as fully functional, regardless of age at death. However, a relatively small proportion of these decedents could be categorized—at the other extreme—as severely restricted.

For most causes, a significantly higher proportion of women than men at the older ages were severely restricted in the last year of life, but the sex-specific relationships between cause and full functionality were less uniform. For those dying of heart disease and of all causes other than heart disease, cancer, and stroke, women were less likely to be fully functional; for those who died of cancer, there were no differences. Among persons dying of cerebrovascular diseases, women appeared more likely to be fully functional, although the differences were not large enough to reach statistical significance.

Health Status and Preexisting Comorbid Conditions

At all ages, decedents with a history of stroke were less likely than most others to be fully functional and more likely to be severely restricted in the last year (Table 2). However, decedents with conditions other than stroke were not consistently less likely to be fully functional or more likely to be severely restricted than were decedents with none of these chronic conditions. In most cases, lower proportions of women than men were fully functional and higher proportions were severely restricted for similar types of preexisting conditions.

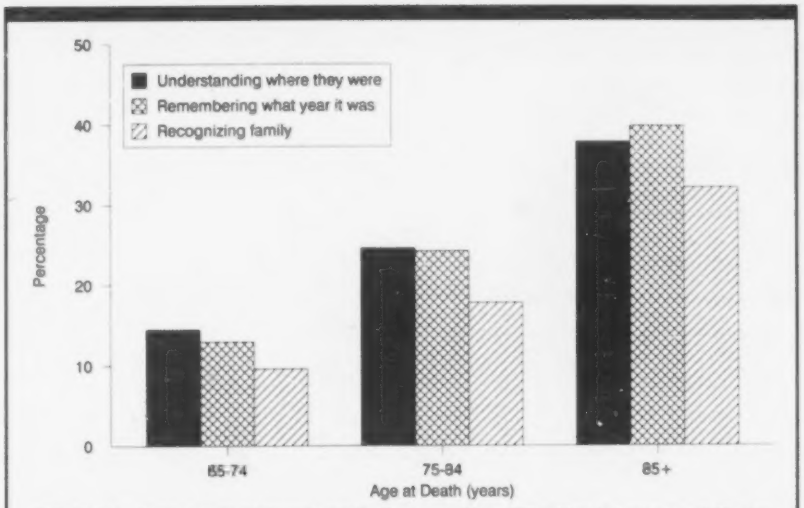

FIGURE 2—Percentage of decedents having cognitive difficulties in last year of life, by age at death.

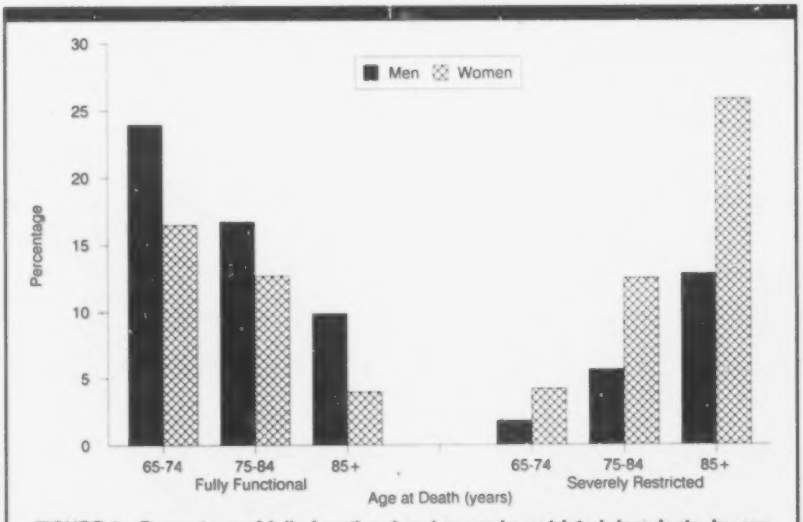

FIGURE 3—Percentage of fully functional and severely restricted decedents, by sex and age at death.

Multivariate Analysis

Sex was highly predictive of health status even after we controlled for age, race, marital status, cause of death, and six preexisting conditions. In the last year of life, women were about 40% less likely than men to have been fully functional and 70% more likely to have been severely restricted (Table 3).

Decedents of races other than White were less likely to be either fully functional or severely restricted, although the odds ratio for these races was significantly different only for the model that examined severe restriction. Marital status at time of death did not appear to be related to full functionality. In contrast, being other than married—widowed, divorced, separated, or never married—doubled the odds of being severely restricted in the last year of life.

The underlying cause of death was associated with the likelihood of being fully functional in the year before death. Those who died from AMI were far more likely to have been fully functional than those who died from any other cause. Decedents with a history of stroke or chronic

[a]A preexisting condition is defined as a condition that existed 12 months prior to death and that was not the underlying cause of death. Categories are not mutually exclusive.

obstructive pulmonary disease, or with a history of two or more preexisting conditions, were less likely to have been fully functional than decedents with none of these conditions. Dying from heart disease other than AMI, dying from stroke or "other causes," and having a history of stroke or of three or more preexisting conditions were all associated with a greater likelihood of very poor functional status than the appropriate reference categories.

We used sex-specific models to evaluate the relative importance of each of the remaining variables for men and women. In general, the direction and strength of the associations were comparable to the first set of models. Few differences were apparent in the fully functional models, except that preexisting conditions seemed to be more important for men. Marital status appeared to be more strongly associated with the likelihood of having been severely restricted in women than in men, whereas cause of death and disease history were more important for men than for women. Women decedents with hypertension and no other preexisting condition were less likely to have been severely restricted than were women decedents with no preexisting conditions.

Discussion

Our results suggest that elderly decedents are fully functional or severely restricted in the 12 months preceding their death in roughly equal proportions, but that the proportion varies with age. Using provisional mortality counts for 1990 (the most recent year for which data are available) and applying the age- and sex-specific prevalences for functionality, we would estimate that about 216 000 elderly decedents experienced little decline in physical independence or mental awareness and few nights in health care facilities during the last year of life.[12] On the other hand, we estimate that 169 000 elderly decedents suffered both mental and physical impairment and were institutionalized for the majority of their last 12 months of life. However, when we excluded the decedents who failed to reach average life expectancy (whose deaths must be regarded as premature no matter what the circumstances), we found that a much larger proportion of decedents required considerable care. Of the oldest decedents—those aged 85 years and older at the time of death—we estimate that about 100 000 died with profound physical impairments and required assistance through much of the last year of life, whereas only about 28 000 were fully functional.

As the oldest-aged population grows in the United States and in other aging societies, the number who are severely disabled may be expected to grow, even with declining mortality rates, unless the present pattern changes. By the year 2000, the number of persons aged 85 years and older who will be severely restricted in their final months may be expected to increase by 50%, given recent official population projections.[13] If health care costs

continue to escalate at present rates, the costs of the care associated with their disabilities may be expected to increase by a much larger percentage.

Our results showing sex as a significant predictor of disability are consistent with findings from recent research on predictors of "healthy aging."[4,5] Guralnik and Kaplan note that although men tend to live shorter lives than women, they are less likely to be functionally impaired.[5] Unfortunately, we cannot determine whether other diseases are responsible for differences by sex in the quality of the last year of life without a more complete inventory of prevalent chronic diseases than is presently on the NMFS. For example, arthritis is a disease that frequently ends in severe disability, and arthritic conditions, whether self-reported or physician-diagnosed, are more common among older women than among older men.[14,15] After controlling for 13 disabling conditions (including arthritis), Verbrugge et al. found that women aged 55 years and older had only slightly higher levels of disability than did men in that age group.[3]

In addition, our definition of "severely restricted" may be responsible for some of the apparent male advantage in functionality, because men are more likely to have a living spouse than are women and are thus more likely to avoid institutionalization in the last year of life. However, when we examined the separate components of the index, we found that female decedents, besides having poorer results than male decedents for ADLs and institutional use, were also more likely to have had cognitive impairments.

Our results also show that factors other than sex are associated with quality of life in the last year. Dying of anything other than a heart attack sharply decreased the likelihood of being fully functional in the 12 months prior to death. Moreover, death from diseases or conditions with prolonged morbid processes that are associated with both physical and mental deterioration, such as stroke and diseases of the heart other than AMI, increased the likelihood that decedents experienced restriction and dependency in their last year of life. Our research suggests that, all other things being equal, the consequence of replacing an earlier death from AMI with a later death from stroke is a greater likelihood of functional disability. This finding suggests that changes in the cause-of-death structure will have an impact on the aggregate assessment of the quality of life in the year before death.

The validity of proxy response will influence the results. Responses from proxies are believed to be most valid when they are based on directly visible phenomena—for example, functional activities, or habits or events such as hospitalizations.[16] The amount of time the proxy spends assisting the patient also influences the proxy's assessment of functional impairment.[17]

To minimize these potential problems of proxy response, we focused on those decedents who were either so healthy or so sick in the last year of life that their condition was a clear matter of record. We evaluated the sensitivity of the results to changes in the definitional criteria by including adjacent categories in the analysis. These changes in definitions resulted in larger numbers of decedents in both the fully functional and the severely restricted groups and, as expected, somewhat lessened the distinction between the two. However, the distinction's persistence suggested that definitional alteration would produce only minor changes in the results.

The NMFS obtained information on the last year of life only. Although it is unlikely that persons who were fully functional in their last year were partially or severely restricted in the years preceding, the reverse may be true: restriction in the final year may follow a long period of functionality. Even though the picture derived from NMFS data is incomplete, we can begin to develop profiles of "successful agers"—men and women who lived into their ninth decade and were fully functional through most of their last year of life—as well as profiles of those who are not so fortunate. We know, for example, that only 25% of the women and 40% of the men who were successful agers had any of the comorbid conditions identified in the NMFS. By contrast, of those who died early with severe restrictions, 66% of the women and more than 90% of the men had at least one of the preexisting conditions. Moreover, persons who died before age 80 after a period of severe restriction were more likely to have died of causes other than AMI than were successful agers.

A valuable addition to a health profile of successful agers would be the quantification of the benefits, if any, obtained from a lifetime of healthy living or risk avoidance. The 1986 NMFS requested information from proxies on the decedent's lifetime smoking, drinking, dietary, and exercise habits and on the decedent's weight. Concerns about data quality and response distribution made it difficult to evaluate the association between successful aging and a multidimensional healthy living index. However, we found that successful agers (defined here as persons who died at age 80 or older and were fully functional) of either sex were less likely than all others to have ever smoked, although the results were significant for men only (data not shown). There was also some evidence that successful agers were less likely than others either to have abused alcohol or to have abstained from it, and that women who were successful agers were less likely than others to have been severely overweight or underweight.

These results are only suggestive. A more fundamental question that cannot be answered here is whether the life-style changes that improve the probability of survival also improve the probability of remaining healthy. Future research should be directed toward answering this important question.

The concept of successful aging should embody both longevity and vitality. That we are experiencing unprecedented gains in life expectancy is well recognized. The quality of life in the 12 months before death provides a potentially important measure of the success or failure of those gains. The next National Mortality Followback Survey, to be conducted in 1993, will provide an important second point for a vector of the quality of aging. □

HMO Membership, Treatment, and Mortality Risk among Prostatic Cancer Patients

Howard P. Greenwald, PhD, and Curtis J. Henke, PhD

ABSTRACT

Objectives. Treatment and mortality risk were compared between prostate cancer patients receiving care in fee-for-service settings and those receiving care in a health maintenance organization (HMO).

Methods. Two samples were obtained from a population-based tumor registry. Patients in the first sample (n = 201) were interviewed shortly after diagnosis to obtain data on income, education, overall health status, and expenditures for health care. These data were combined with information from the tumor registry on cancer stage, age, treatment, place of residence, and source of care. Only tumor registry data were obtained for most patients in the second sample (n = 962). For both samples, survival time was monitored for up to 80 months.

Results. Multivariate analysis of data from the interviewed sample indicated that HMO patients were less likely to receive surgery but more likely to receive radiation therapy than were those in fee-for-service settings. Mortality risk was lower for the HMO patients than for those in fee-for-service plans. Findings based on the second sample were nearly identical.

Conclusions. This study suggests that HMOs may offer important advantages to lower-income patients at risk for specific life-threatening diseases. (*Am J Public Health.* 1992;82: 1099–1104)

Introduction

Government, business, and private citizens alike look increasingly to the health maintenance organization (HMO) as a source of affordable, high-quality health care. Supporters of HMOs argue that these organizations deliver care more economically than the fee-for-service system[1–5] and provide care of a quality acceptable to a wide variety of individuals.[6] Several commentators and researchers, however, have suggested that HMOs reduce the quality of care available to at least some consumers.[7,8] One major study reported that low-income HMO members in poor health experience more serious symptoms and greater mortality risk than do those in a "free" fee-for-service plan,[9] although a later analysis indicated no differences.[10] A study of cancer patients reported that HMO members wait longer between diagnosis and the beginning of treatment than do those in fee-for-service.[11]

In this study we examined the treatment and survival of prostatic cancer patients in a large, well-established HMO and in fee-for-service settings in the surrounding community. We compared (1) stage at detection, (2) primary cancer treatment received during the 6 months following initial diagnosis, and (3) mortality risk among patients in the HMO and fee-for-service plans. These areas are directly pertinent to the quality of care. Stage at detection and treatment are important aspects of the process of care; mortality (or its avoidance) is perhaps the key dimension of outcome.

High-quality care of patients with prostatic cancer is an important objective for health professionals. In 1990, the American Cancer Society projected that prostatic cancer would be the most commonly occurring malignancy among males in the United States and that it would account for over 10% of male cancer deaths.[12] The efficacy of many widely used treatment interventions is disputed.[13] However, a recent comprehensive review of cancer mortality indicates that real survival rates, that is, those not explainable merely as statistical artifacts associated with earlier detection, have risen over the past four decades because of improved tumor evaluation, treatment planning, and radiation therapy.[14]

Methods

The investigators analyzed data on two overlapping samples of persons with prostatic cancer. To obtain the first sample (sample 1), they identified and interviewed persons in King and Pierce Counties, Washington (whose major cities are Seattle and Tacoma), who were originally diagnosed with this malignancy between 1980 and 1982. Patients were identified through the Cancer Surveillance System (CSS), a population-based tumor registry maintained by the Fred Hutchinson Cancer Research Center in Seattle. Operating under contract with the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) Program, the CSS attempts to register all cancer cases that occur in a 13-county area in north-

western Washington State within 3 months of diagnosis. All individuals identified as HMO members belonged to Group Health Cooperative of Puget Sound, the only major HMO operating in the area in the early 1980s.[15]

Clinical and demographic information was obtained from the CSS, supplemented by face-to-face interviews in sample 1. CSS records provided data on stage, date of diagnosis, location of residence, source of care, diagnostic procedures, initial cancer therapy, and date of death in the event of mortality. Face-to-face interviews were required to obtain data on several patient characteristics capable of affecting the process and outcome of care, such as income, education, direct payment for health services, and general health status. Although previous studies using CSS data exclusively have addressed income and education,[16] they have inferred characteristics of individuals on the basis of their places of residence, a procedure of uncertain accuracy.

The CSS constitutes a highly reliable means of identifying cancer patients and monitoring their survival. An evaluation of the CSS has recently demonstrated that fewer than 2.5% of the cancer cases in its catchment area are missed by the registry.[17] The National Cancer Institute requires the registry to update the status of all living patients within 18 months following diagnosis or last contact.[18] This update is accomplished by contacting the hospitals at which patients were originally treated and the physicians who cared for them[19] and by monitoring the state's computerized file of death certificates.[20]

To select subjects for sample 1, the investigators used a quota sampling procedure with the goal of finding 200 consecutive patients newly diagnosed with prostatic cancer in the pertinent geographical area. Because the interview schedule was long and required significant effort to administer and complete, this sample was restricted to a limited number of patients, all 80 years of age and younger. Human-subjects considerations required the investigators to obtain the physician's permission before his or her patient could be asked for an interview. Physician permission was requested for 377 patients and received for 297. Most refusals (about 75) came from a small number of non-HMO physicians who explained that they were unwilling to allocate staff time or that they disputed the need for a study of pain and quality of life among cancer patients (the initial purpose of the data collection). These physicians refused the investigators access to all of their patients; they did not selectively grant permission to contact some while withholding it for others. The researchers succeeded in contacting 264 patients and obtained sufficient interview data from 201 for inclusion in the study.

For the second sample (sample 2), the investigators selected 1000 consecutive cases of newly diagnosed prostatic cancer from the CSS that were entered between 1981 and 1982, when most of the interviewing of the first sample took place. For sample 2, only data from the CSS records were obtained. Because consent was required from neither the physician nor the patient, data from all 1000 cases were available. (Data from 38 patients who were followed by the CSS for less than 1 month were not included in the analyses.)

To assess bias in sample 1, the investigators compared subjects in sample 2 who were interviewed (and thus also included in sample 1) with subjects in sample 2 who were not interviewed. Among those not interviewed in sample 2, subjects comparable to those in sample 1 were those 80 years of age and younger who had been followed for at least 2 months by the CSS (n = 784). The 2-month criterion was used for this comparison to eliminate those who would have been unavailable for interview because they had died very soon after diagnosis or because diagnosis had been made at autopsy. A total of 174 subjects in sample 2 were also included in sample 1. Those interviewed tended to be younger (mean age: interviewed = 67.5 years, SE = .56; not interviewed = 68.9 years, SE = .29), were more likely to live in an urban census tract (percentage urban: interviewed = 89.7, SE = 2.32; not interviewed = 81.1, SE = 1.58), and were more likely to have been diagnosed at a higher stage (percentage stage II: interviewed = 16.1, SE = 2.93; not interviewed = 12.1, SE = 1.32; percentage stage III: interviewed = 27.6, SE = 3.40; not interviewed = 15.6, SE = 1.47). HMO patients were overrepresented among those interviewed (percentage in the HMO: interviewed = 20.1, SE = 3.08; not interviewed = 6.6, SE = 1.00), probably because no HMO physician refused access to all of his or her patients.

The investigators used ordered logistic regression to assess the relation of HMO membership to stage at detection, independent of the patient's background characteristics (age, income, education, and place of residence). Binary logistic regression was used to predict dichotomous variables indicating whether or not a specific type of treatment—surgery, radiation therapy, chemotherapy, or multimodal treatment (defined as therapy using two or more modalities)—was received. Dichotomous logistic analysis was appropriate here because individual treatment modalities were not mutually exclusive. The Cox proportional hazards model[21] was used to assess the effect of HMO membership on mortality risk independent of individual background characteristics.

Results

Table 1 presents means and standard errors for variables in the analyses that follow. For sample 2, the figures presented in Table 1 and the tables that follow are based on 962 patients. Among the original 1000 patients in sample 2, 38 patients were followed by the CSS for less than 1 month. Because these patients presumably were diagnosed when terminal or at autopsy, the data they generated did not appear to be pertinent to a study of survival and related treatment.

The data shown in Table 1 suggest that cancer stage does not systematically vary across health care source. Ordered logistic regression confirms this initial observation. In this and subsequent tables, cancer stage (stage at diagnosis) is represented as a series of dichotomous variables (stage I = local, II = regional, III = distant spread), coded 0 or 1 as appropriate for each observation. In an equation predicting stage that was based on sample 1 and included age, urban residence, education, and income on the right-hand side, HMO membership had a coefficient of .183 (SE = .352, P = .683). In an equation based on sample 2 that included age and urban residence, HMO membership had a coefficient of .231 (SE = .243, P = .348).

Table 2 summarizes a binary logistic regression analysis of data from sample 1 on key therapies used for prostatic cancer. By statistically significant margins, HMO members were less likely to receive surgery but more likely to receive radiation therapy than were those in fee-for-service plans. No statistically significant relations are visible between HMO membership and hormone or multimodal treatment. In these equations and those presented below, stage is represented by two dichotomous variables (stage II and stage III); the coefficients on these variables reflect differences in the dependent variable from stage I, which is omitted from the equations.

Tables 3 and 4 present Cox proportional hazards models predicting mortality

[a] Standard errors are in parentheses.

risk based on sample 1. Four variables in Table 3 have statistically significant relationships with mortality risk. HMO membership predicts a lower risk of mortality: individuals in the HMO apparently faced a risk of dying in any given month following diagnosis that was about 38% of that of fee-for-service patients. Educational level predicts mortality risk, each year of education lowering mortality risk by about 9%. As expected, the two variables representing cancer stage are strong predictors of mortality risk.

Figure 1 presents mortality curves for HMO and fee-for-service patients. These curves illustrate relative risks of HMO and fee-for-service patients in each month following diagnosis. Part A of Figure 1 compares the observed proportions of HMO and fee-for-service patients surviving at the beginning of each month. Part B of Figure 1 presents mortality curves based on estimates of risk controlled for disease and background variables using the Cox equation summarized in Table 3.

Table 4 presents a model that assesses the effects of family income level (low, middle, and high) and of HMO membership within specific income categories. For the purposes of this study, individuals reporting family incomes of under $20 000 in the year preceding their interviews are considered to have low incomes; those with incomes between $20 000 and $34 999 are considered to have middle incomes; those with incomes over $35 000 are considered to have high incomes. The equation includes dichotomous variables representing membership in the middle-

income and high-income categories. Coefficients on these variables represent differences between each income category and low income, a variable omitted from the equation. No significant relationship between either income category and mortality risk is observed.

The table does, however, indicate important income-related differences in the effects of HMO membership on mortality. The equation summarized here includes interaction terms representing HMO membership within the low-, middle-, and high-income categories. Coefficients on these interaction terms indicate the difference in mortality risk of HMO versus fee-for-service patients within each income category. Among low-income patients, mortality risk is lower for HMO members than for those in fee-for-service by a statistically significant margin. No statistically significant differences are observed for patients in the middle- and high-income categories. Figure 2 illustrates these relationships, presenting survival curves computed on the basis of the Cox equations presented in Table 4.

A similar equation including two measures of general health status—an abbreviated (5-point) Karnofsky Scale and the Sickness Impact Profile Scoring Dimension 1[22]—produces results very similar to those presented in Table 4.

To identify patients in "free" fee-for-service settings, the interviewers asked subjects in the face-to-face interviews whether they had made any direct payment for medical care other than insurance premiums in the 12 months before their interviews. A Cox proportional hazards model, similar to the one represented in Table 4, estimated only for individuals reporting no direct payment (n = 88) indicates results very similar to those shown in Table 4. The mortality risk ratio for low-income HMO members versus those in "free" fee-for-service plans was .176 (95% CI = .054, .576), significant at the .01 level. The risk ratio for low-income HMO members versus fee-for-service patients obtained on the basis of a sample segment (n = 157) of HMO members and fee-for-service patients reporting direct payment was .181 (95% CI = .059, .561), $P < .01$.

Many practitioners believe that the implications of prostatic cancer for life expectancy are very different for older and younger patients.[23] But among persons 72 years of age and younger (n = 136), the risk ratio for the low-income HMO members versus fee-for-service patients was .100 (95% CI = .012, .818), $P < .05$. A similar finding was obtained for those aged 65 and younger, although this finding was not statistically significant owing to the small number of observations (n = 67).

Tables 5 and 6 present findings from analyses similar to those reported above but based on data from sample 2. In these tables only age, urban residence, and stage appear as control variables; the CSS does not include information on income, education, or general health status. The results shown in Table 5 are very similar to those shown in Table 2: HMO members were less likely to receive surgery and more likely to receive radiation therapy. HMO members also were less likely to receive hormone therapy than were those in fee-for-service plans. Table 6 presents results very similar to those shown in Table 3: HMO members experience a mortality risk lower than that of fee-for-service patients.

Discussion

In both samples examined in this study, HMO patients were less likely to receive surgery and more likely to receive radiation therapy than were those in fee-for-service plans. In one of the samples analyzed, HMO members also appeared less likely to receive hormone therapy. Mortality risk was lower for the HMO members, a difference that was greatest among those in the lowest income category used in the analysis.

Several features of this study require discussion before conclusions may be drawn. First, the study used a nonexperimental design, admitting the possibility that subjects who selected the HMO, pay fee-for-service, and free fee-for-service plans for their care may have differed in health status, health risks, and behavioral predispositions. Acknowledging this possibility, the investigators included key patient characteristics other than source of care in the analysis of mortality risk. The relationships reported here between

HMO membership and mortality risk remain statistically significant even after these dimensions have been held constant according to widely used methods of assessment.

Because cases in sample 1 differ from comparable cases in sample 2 on important dimensions, findings based on sample 1 cannot be unequivocably generalized to all persons in King and Pierce Counties who contracted prostatic cancer between 1980 and 1982. Analysis of sample 2, however, largely remedies this problem. This sample included all newly diagnosed prostatic cancer patients entered in the CSS during the specified period. Because the number of cases the CSS fails to register is quite small, any unknown bias is likely to be minor. Except for the interaction between low income and HMO membership and its effect on mortality (income is not recorded in the CSS), the analysis of sample 2 confirms findings based on Sample 1.

Another issue concerns the unusual nature of the Group Health Cooperative of Puget Sound. The Group Health Cooperative is one of the largest and oldest HMOs in the United States, serves as a site for important research, and enjoys national recognition. The degree to which the unique qualities of the Group Health Cooperative explain its patients' apparent survival advantage is uncertain.

The categories used by the CSS to denote stage differ from those most often employed in clinical practice and investigations of prostatic cancer. Several more detailed, multidimensional staging systems are in widespread use.[13] The validity of the CSS stage as a variable representing overall disease dissemination is confirmed by its strong relationship to mortality risk in the Cox models presented above. Nevertheless, use of a different system to represent stage might have altered the results reported here.

The data reported here are not sufficiently detailed to demonstrate that the observed differences in mortality risk arise from prostatic cancer or from differential rates of success in its treatment. Like many studies of cancer mortality,[24–26] this investigation used all-cause mortality as its principal outcome variable. As in the general population of men with prostatic cancer, in which persons of advanced age are strongly represented, much of the mortality observed here is likely to have come from other causes.[27]

Despite this study's limitations, the observations reported here remain pertinent to the discussion of quality of care in HMOs versus fee-for-service plans. The finding that HMO patients are less likely to receive surgery and more likely to receive radiation therapy is consistent with reports that HMOs favor outpatient care. The results of this study contradict the belief that HMOs undertreat their patients and that low-income individuals with established health problems obtain less favorable outcomes in HMOs than in fee-for-service plans. These findings should encourage policymakers to continue viewing the HMO as a desirable alternative to traditional fee-for-service plans, particularly for low-income persons. Research published elsewhere[28] suggests that treatment in an HMO may help rem-

edy survival disadvantages faced by low-income people with cancers other than prostatic. It appears that the essential features of a well-established HMO enable persons predisposed to seeking appropriate care to do so, and that they promote access to basic medical services. Among patients similar to those studied here—those who have a major, definable health problem that is likely to coincide with a variety of eventual comorbidities—these factors appear conducive to survival. □

Acknowledgments

Collection of data was supported in part by the National Cancer Institute under Grant 5 R18 CA 32564-02. Data analysis took place under funding from the American Cancer Society (Grants PBR-11 and PDT-393).

Car Size or Car Mass: Which Has Greater Influence on Fatality Risk?

Leonard Evans, DPhil, and Michael C. Frick, MA

ABSTRACT

Objectives. Proposed increases in corporate average fuel economy standards would probably lead to lighter cars. Well-established relationships between occupant risk and car mass predict consequent additional casualties. However, if size, not mass, is the causative factor in these relationships, then decreasing car mass need not increase risk. This study examines whether mass or size is the causative factor.

Methods. Data from the Fatal Accident Reporting System are used to explore relationships between car mass, car size (as represented by wheelbase), and driver fatality risk in two-car crashes.

Results. When cars of identical (or similar) wheelbase but different mass crash into each other, driver fatality risk depends strongly on mass; the relationship is quantitatively similar to that found in studies that ignore wheelbase. On the other hand, when cars of similar mass but different wheelbase crash into each other, the data reveal no dependence of driver fatality risk on wheelbase.

Conclusions. Mass is the dominant causative factor in relationships between driver risk and car size in two-car crashes, with size, as such, playing at most a secondary role. Reducing car mass increases occupant risk. (*Am J Public Health.* 1992;82: 1105–1112)

Introduction

Relationships between occupant injury risk in a car crash and the mass of the car have been firmly established in many studies conducted over the last few decades[1], and continue to be refined.[2,3] General relationships between risk and mass can never, by themselves, establish that mass is a causative factor, because other vehicle attributes, particularly car size, are so strongly correlated with mass. Some specific findings from crash data can help illuminate causal factors. The higher rollover rates of lighter cars[4–6] appear to be caused by size rather than mass because as cars become smaller, so does their track width (the distance between the left and right wheels), with consequent reductions in rollover resistance. Another effect due to size rather than mass is the higher risk of death and injury when light cars crash into light cars compared with when heavy cars crash into heavy cars[1,7,8]; broad dynamical behavior of identical-mass cars crashing into each other should not be much influenced by their mass. Proposed increases in corporate average fuel economy are expected to lead to reductions in the mass of the average car. Some have speculated that if size were the dominant causative factor, then reductions in mass need not necessarily lead to increased occupant risk if vehicle size can be maintained constant by, for example, the use of lighter weight materials.

The purpose of the present work is to explore further the relationship between car mass and car size and its relevance to driver fatality risk. Car size is represented by wheelbase. The following four questions will be addressed, in each case for newer cars (model year 1980 or after) and for older cars (model year 1979 or before): What is the relationship between (1) mass and wheelbase? (2) driver fatality risk and wheelbase? (3) driver fatality risk and mass for cars of the same wheelbase? and (4) driver fatality risk and wheelbase for cars of similar mass?

Data

The Fatal Accident Reporting System is a computerized data file maintained by the National Highway Traffic Safety Administration containing detailed information on all traffic crashes occurring in the United States since January 1, 1975, in which anyone was killed.[9] The present investigation uses data for two-car crashes in which at least one of the drivers was killed and the mass of each car was coded. The Fatal Accident Reporting System records for the years 1975 through 1989 contain 38 465 such crashes, with 38 268 of these involving cars with coded wheelbases. Some analyses use a 25 246 crash subset, formed by excluding any crash for which more than one wheelbase was coded for either car (to reflect different versions of the same model) and any crash for which the wheelbase of each of the involved cars was the same. The analysis was performed in terms of wheelbase, rather than arguably more appropriate size indicators such as the bumper-to-bumper length, because wheelbase is the only measure of vehicle size coded directly in Fatal Accident Reporting System data.

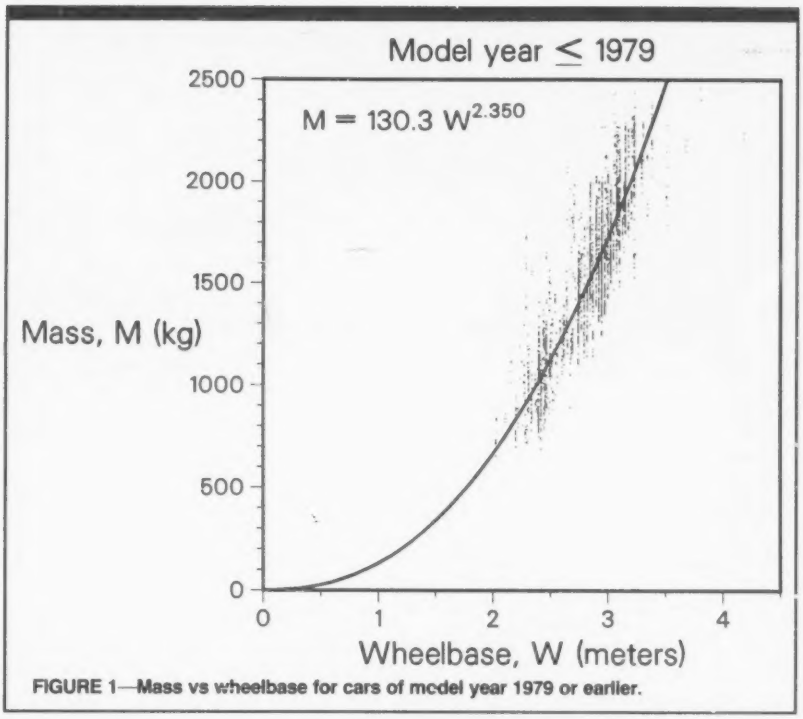

FIGURE 1—Mass vs wheelbase for cars of model year 1979 or earlier.

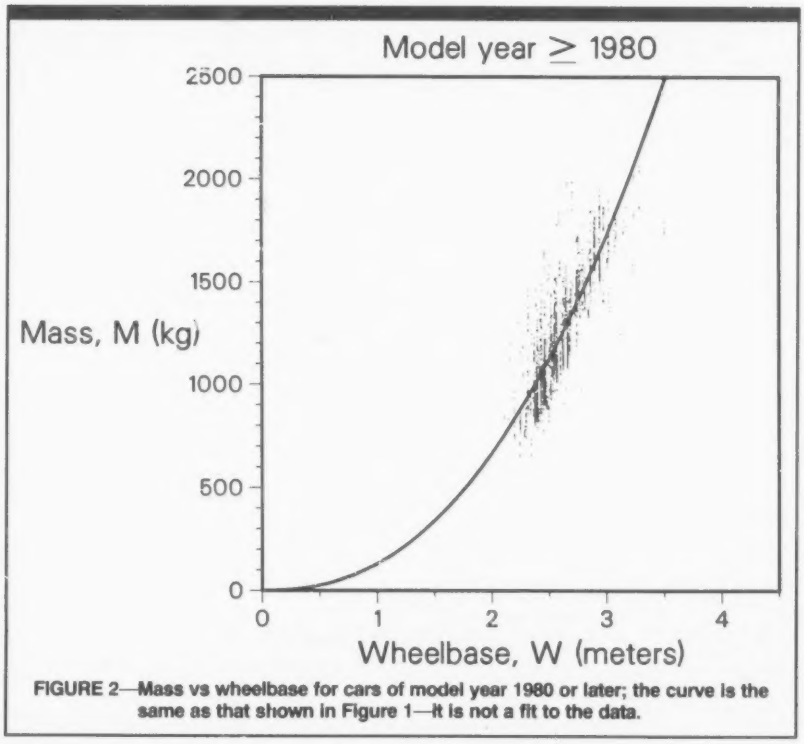

FIGURE 2—Mass vs wheelbase for cars of model year 1980 or later; the curve is the same as that shown in Figure 1—it is not a fit to the data.

Relationship between Mass and Size

To illuminate the relationship between car size and car mass, consider a hypothetical construct in which all cars are made from material with the same density. If cars were of identical shape, differing only by a scale factor, then mass would be proportional to any linear dimension to the power three. However, regardless of their size, cars must be of sufficient height to accommodate seated humans. If all cars had the same height, so that only length and breadth varied, then mass would be proportional to length (or breadth) to the power two. Real cars are likely to be intermediate between these two hypothetical cases, suggesting a relationship between mass and wheelbase of the form

$$M = \alpha W^{\beta}, \quad (1)$$

where M is the mass of the car, W is a linear dimension (other than height), and α and β are constants; the comments above lead us to expect β to be between 2 and 3.

Figure–1 shows mass vs wheelbase for cars of model year 1979 or earlier. One point is plotted for each of the 4714 unique combinations of mass and wheelbase, regardless of how many individual cars or fatalities are associated with that combination. The least squares fit of Equation 1 (in its logarithmic form) to the data gives

$$\alpha = (130.3 \pm 2.2) \quad (2)$$

and

$$\beta = (2.350 \pm 0.017). \quad (3)$$

The above value of α applies for M in kilograms and W in meters. If M is measured in pounds and W in inches, then $\alpha = 0.05124$.

The plot for cars of model year 1980 or later (3824 unique mass/wheelbase combinations) is shown in Figure 2. The least squares fit to Equation 1 gives

$$\alpha = (109.1 \pm 2.5) \quad (4)$$

and

$$\beta = (2.514 \pm 0.024). \quad (5)$$

The parameter α is smaller for the newer than for the older cars, whereas β is larger for the newer cars, in both cases the difference being statistically significant. However, because α and β are themselves so highly correlated (increasing one while decreasing the other need have only a small effect on the goodness of fit), these differences do not appear to indicate any important difference in the relationships for older and newer cars. In fact, the relationships cross at $W = 2.95$ m, $M = 1650$ kg. For $W < 2.95$ m, lower masses are calculated for newer cars (40

kg lower at $W = 2.1$ m, the minimum W in Figure 2), whereas at $W > 2.95$ higher masses are calculated for newer cars (71 kg higher at $W = 3.5$ m).

In order to examine better any changes from the older to the newer cars, the curve shown in Figure 2 is the same one shown in Figure 1 (i.e., Equation 1 with the parameters for the older cars given in Equations 2 and 3). The data for newer cars show no obvious systematic departures from the curve derived for the older cars. Thus, there does not appear to be any systematic reduction in mass apparent above the considerable scatter in the data for newer compared with older cars of the same wheelbase.

Driver Fatality Risk in Two-Car Crashes and Wheelbase

An earlier study[2] examined how the ratio of driver fatality risk in each car involved in a two-car crash depended on the ratio of the masses of the involved cars. Here we apply a parallel analysis but use the ratio of the wheelbases of the involved cars rather than the masses. In analogy with the prior mass ratio μ, we define a "wheelbase ratio," ν, for crashes between two cars of different wheelbase as

$$(6)\quad \nu = \frac{\text{Wheelbase of the Car with Longer Wheelbase}}{\text{Wheelbase of the Car with Shorter Wheelbase}}.$$

We define a driver fatality ratio, R, as

$$(7)\quad R = \frac{\text{Driver Fatalities in the Car with Shorter Wheelbase}}{\text{Driver Fatalities in the Car with Longer Wheelbase}}.$$

Older Model Year Cars

Figure 3 shows R vs ν for cars of model year 1979 or earlier. In analogy with the mass ratio study,[2] a weighted least squares fit to $\log(R) = w \log(\nu)$ is used to derive

$$(8)\quad R = \nu^w.$$

The parameter w derived from the fit to the data in Figure 3 is

$$(9)\quad w = 8.61 \pm 0.23.$$

Thus, the fatality rate increases as more than the eighth power of the wheelbase. It is rare to find so large an exponent in any relationship between observed quantities. The values of w and Δw in Equation 9, together with values derived by fitting Equation 8 to other sets of the data, are displayed in Table 1. The number of categories into which the data were divided for each analysis was the number that minimized $\Delta w/w$, subject to the restriction that no point be based on fewer than 50 fatalities.

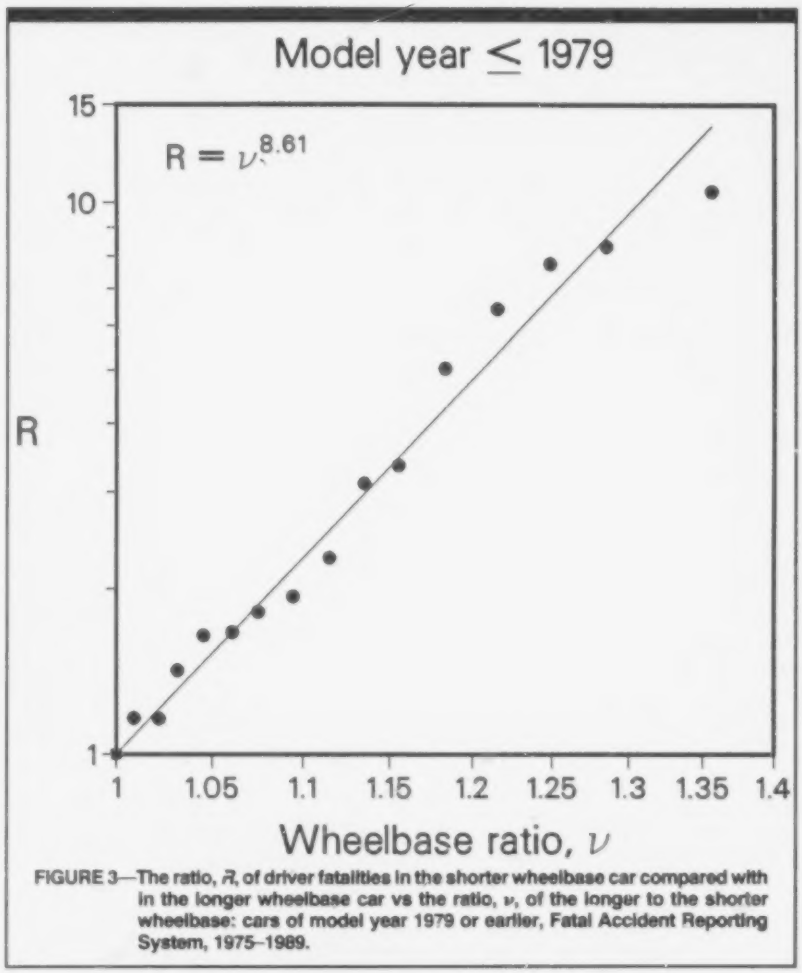

FIGURE 3—The ratio, R, of driver fatalities in the shorter wheelbase car compared with in the longer wheelbase car vs the ratio, ν, of the longer to the shorter wheelbase: cars of model year 1979 or earlier, Fatal Accident Reporting System, 1975–1989.

TABLE 1—Characteristics of the Relationship $R = \nu^w$ for Various Sets of Data

	No. of Crashes	No. of Fatalities	$w \pm \Delta w$
All cars	25 246	27 396	8.40 ± 0.16
Model year ≤ 1979 (Figure 3)	13 363	14 501	8.61 ± 0.23
Model year ≥ 1980 (Figure 4)	4351	4802	6.76 ± 0.24
Belted drivers, all cars	1397	1478	8.75 ± 0.60
Belted drivers, model year ≤ 1979	167	172	9.29 ± 0.90
Belted drivers, model year ≥ 1980	684	736	6.83 ± 0.83

Note. The numbers of categories of ν (number of points plotted in Figures 3–4) for the six cases shown are, from top to bottom, 18, 15, 12, 14, 3, and 8.

In Evans and Frick[2] the ratio, R, of driver fatality risk in the lighter of two cars compared with risk in the heavier car was related to the ratio, μ, of the mass of the heavier to that of the lighter car according to

$$(10)\quad R = \mu^w.$$

We use the same symbol R to represent

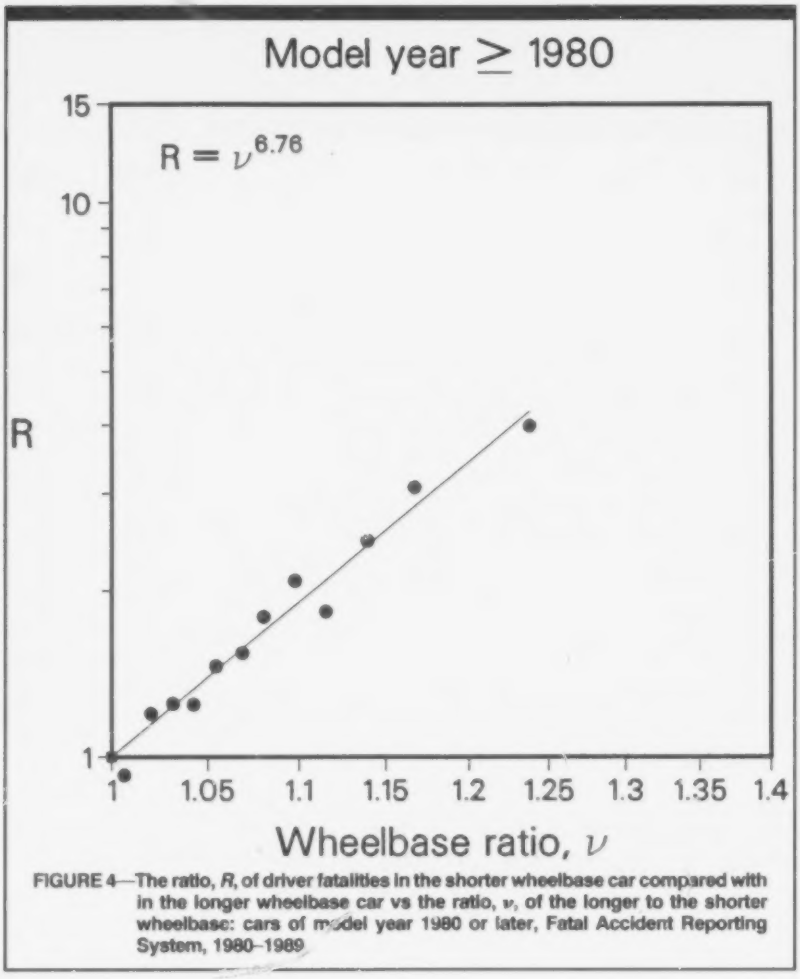

FIGURE 4—The ratio, *R*, of driver fatalities in the shorter wheelbase car compared with in the longer wheelbase car vs the ratio, *ν*, of the longer to the shorter wheelbase: cars of model year 1980 or later, Fatal Accident Reporting System, 1980–1989.

driver fatality risk ratios, although in Equation 10 the comparison is for cars of different mass, whereas in the earlier cases the comparison was for cars of different wheelbase; the context will always make it clear whether the comparison is based on mass or wheelbase.

The value of u (from Table 1 of Evans and Frick[2]) for cars of model year 1979 or earlier is

$$u = 3.73 \pm 0.04. \quad (11)$$

The much stronger relationship with wheelbase ratio than with mass ratio, as reflected by an exponent of 8.6 compared with 3.73, should not be interpreted to imply that wheelbase is a better explainer of fatality ratio than mass or that size plays a more direct causative role than weight. Rather, the relationship between fatality ratio and wheelbase ratio follows directly from the relationships between mass and wheelbase, and between fatality ratio and mass ratio, and can be inferred directly from Equation 10 (with the aid of Equations 1, 3, and 11) to give

$$R = \mu^{3.73} = \left(\frac{M_2}{M_1}\right)^{3.73} \quad (12)$$

$$= \left(\frac{\alpha W_2^{2.35}}{\alpha W_1^{2.35}}\right)^{3.73}$$

$$= (\nu^{2.35})^{3.73} = \nu^{8.8},$$

where M_2 and M_1 are the masses of the heavier and lighter cars defining the mass ratio μ and W_2 and W_1 are the corresponding wheelbases. Note how close the inferred exponent of 8.8 is to the directly obtained value of 8.6. Thus, the higher exponent for wheelbase than for mass reflects merely how steeply mass increases with increasing wheelbase. The parameter w is necessarily larger than the parameter u by about a factor of 2.35, so the difference in the magnitudes of the w and u parameters offers no illumination on the relative roles of size and weight in car safety. It seems likely that an inappropriate interpretation of larger parameters in regressions on size compared with regressions on mass could have contributed to suggestions[10] that size was a more important causative factor than mass.

Newer Model Year Cars

The data for driver fatality ratio vs wheelbase ratio for cars of model year 1980 or later are shown in Figure 4. The lower value of w, namely

$$w = 6.76 \pm 0.24, \quad (13)$$

is to be expected because the mass ratio analysis showed a lesser dependence for newer model year cars.

Applying a computation similar to that in Equation 12 to the mass ratio equation (Figure 4 of Evans and Frick[2]) and Equation 5 gives an inferred fatality risk ratio of

$$(\nu^{2.51})^{2.75} = \nu^{6.9}, \quad (14)$$

in close agreement with the directly observed value from Figure 4 of 6.8.

Effect of Safety Belt Use

The values of w and Δw in Table 1 for belted drivers indicate that the influence of wheelbase ratio on driver fatality risk is similar for belted and for all drivers (mainly unbelted). This further supports findings in three earlier studies (pp. 74 and 236 of Evans[1]; Evans and Frick[2]) that safety belt effectiveness does not depend systematically on car size. If all occupants are belted, the proportionate increase in risk in the smaller car remains similar.

How Does Fatality Risk Depend on Mass When Cars Have the Same Wheelbase?

Figures 1 and 2 show many cases of cars with the same wheelbase but different masses. This enables us to separate out effects of size and mass in a direct and straightforward manner.

Considering all two-car crashes, without regard to model year, there were 862 crashes in which the wheelbase of each of the involved cars was the same but the masses were different. In these crashes, 574 drivers in the lighter car were killed, compared with 395 driver fatalities

in the heavier car. Thus, for identical wheelbase, driver fatality risk in the lighter car was 1.45 ± 0.09 times the risk in the heavier car, where the standard error is computed using Equation 7-4 of Evans.[1] The 862 values of mass ratio are all fairly close to one, with an average value of 1.081. Substituting $\mu = 1.081$ into Equation 10 with $u = 3.53$ (Figure 1 of Evans and Frick[2]) estimates a fatality ratio of 1.32, comparable to the observed 1.45 value.

The cases in which the wheelbase of each car was identical are examined as a function of mass ratio in Figure 5. The resulting figure may be compared with many relationships between fatality ratio and mass ratio.[2] The greater noise is to be expected in view of the narrow range of values of μ; the error limits indicate one standard error for each of the plotted points. The value of u, namely 3.8 ± 0.6, is consistent with the value 3.53 derived from 38 382 crashes (Figure 1 of Evans and Frick[2]) examined as a function of mass ratio without regard to wheelbase. This comparison identifies mass unambiguously as an important factor exercising a large influence on fatality risk. Size (as represented by wheelbase) can have no effect on the relationship in Figure 5, because for each crash the wheelbase of each of the involved cars is the same. If the analysis is confined to cars of model year 1979 or earlier, 573 of the original 862 crashes are preserved. These give $u = 4.3 + 0.6$, which is consistent with the value 3.73 for 23 012 crashes without regard to wheelbase.[2]

Confining the analysis to crashes between two cars of model year 1980 or later leaves 168 crashes that led to 102 driver fatalities in lighter cars compared with 88 in heavier cars, for a ratio of 1.16 ± 0.17. Substituting $\mu = 1.051$, the average mass ratio, into Equation 10 with $u = 2.75$ (Figure 4 of Evans and Frick[2]) computes an expected driver fatality ratio of 1.15. The difference between the computed ratio and unity is too small to be detected reliably with the available sample size (the closeness of the observed and expected values is fortuitous given the large uncertainty).

In order to increase sample sizes, the restriction that the wheelbases be equal was replaced by a restriction that they not differ by more than some small amount. As this amount is increased, sample sizes increase, but so also does the possibility that the difference in wheelbase is itself influencing the driver fatality risk ratio. There were 280 crashes involving two cars

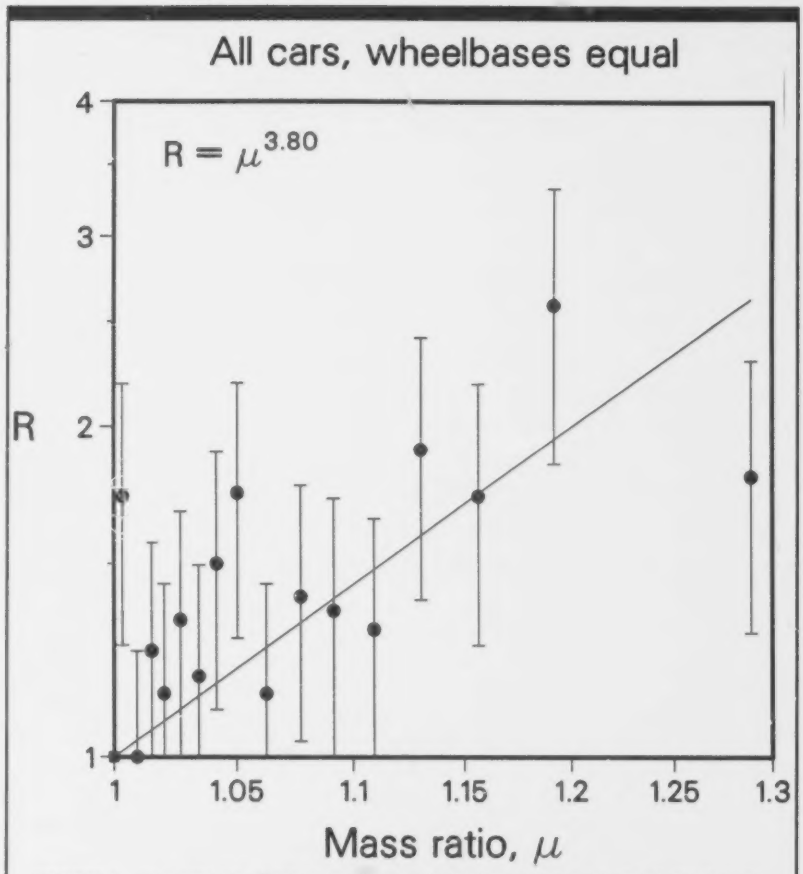

FIGURE 5—The ratio, *R*, of driver fatalities in the lighter compared with in the heavier car vs the ratio, μ, of the mass of the heavier to the mass of the lighter car for crashes between cars with identical wheelbase: data for cars of any model year, Fatal Accident Reporting System, 1975–1989.

of model year 1980 or later whose wheelbases differed by less than 1 cm, leading to 183 driver fatalities in the lighter cars compared with 133 in heavier cars. Very little of this difference seems attributable to the differences in the wheelbases, because a 1-cm difference in a 2-m-wheelbase small car gives $\nu = 1.005$, which (from the relationship in Figure 4) would produce a 3.4% effect on driver fatality ratio. This is small compared with the (38 ± 16)% difference observed.

Figure 6 shows fatality risk ratio vs mass ratio for the 280 crashes in which the wheelbases of the two cars involved differed by less than 1 cm. The value of u, 3.76 ± 0.89, is consistent with the value of 2.75 ± 0.11 for cars of model year 1980 or later.[2] Given the uncertainty, the most that can be concluded is that when the wheelbase remains fairly constant, the data provide no indication that fatality risk ratio increases with mass ratio less strongly than when wheelbase is ignored. If wheelbase and mass were exercising a shared influence, then when wheelbase is fixed one would expect the influence of mass to be reduced.

The analyses for cars of all model years, for older cars, and for newer cars all consistently lead to the same conclusion. When wheelbase is held constant, mass influences driver fatality ratio just as strongly as when wheelbase varies. This provides strong evidence that mass, as such, has a large influence on driver fatality risk.

How Does Fatality Risk Depend on Wheelbase When Cars Have Similar Mass?

The above analysis suggests a corresponding one to address the question "If the mass is the same, how does wheelbase ratio affect fatality risk?" While there are usable sample sizes of cars coded with identical wheelbase but different mass, there were only eight crashes between

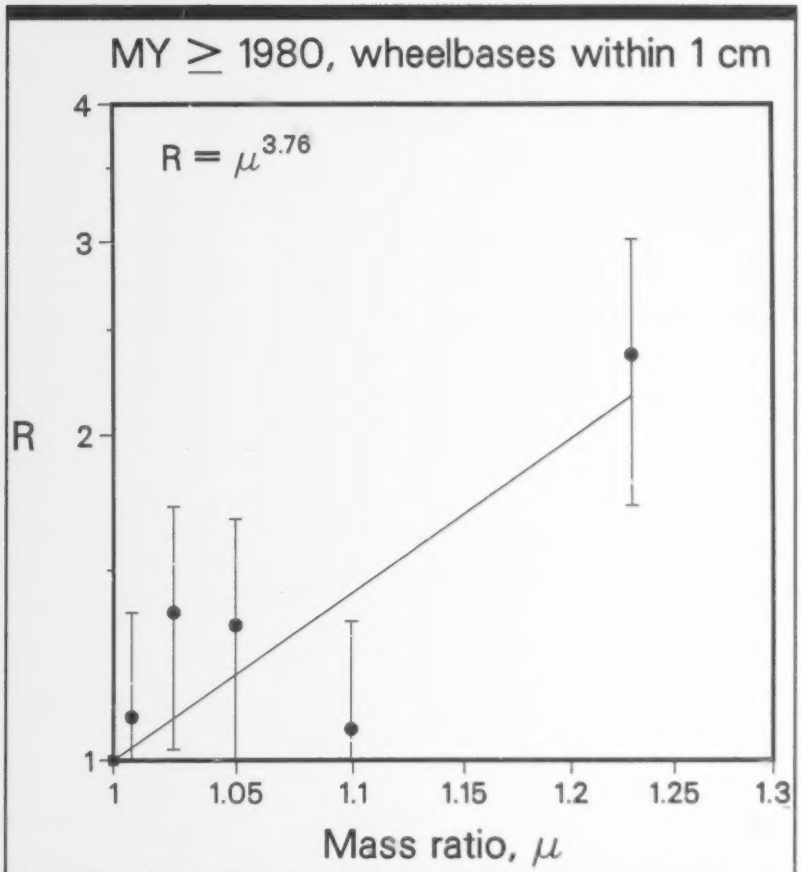

FIGURE 6—The ratio, *R*, of driver fatalities in the lighter compared with in the heavier car vs the ratio, μ, of the mass of the heavier to the mass of the lighter car for crashes between cars with wheelbases differing by less than 1 cm: cars of model year 1980 or later, Fatal Accident Reporting System, 1980–1989.

TABLE 2—Crashes between Cars of Similar Mass: Examination of the Influence of Wheelbase for Cars of Model Year 1979 or Earlier

Maximum Difference between Car Masses, kg	No. of Crashes	Fatalities in: Shorter Car	Fatalities in: Longer Car	Ratio ± SE	$\bar{\nu}$
20	321	173	185	0.935 ± 0.099	1.044
30	470	257	275	0.935 ± 0.081	1.043
40	633	351	365	0.962 ± 0.072	1.043
50	780	438	455	0.963 ± 0.064	1.043
70	1084	610	622	0.981 ± 0.056	1.043
100	1549	876	878	0.998 ± 0.048	1.044
150	2337	1339	1302	1.028 ± 0.040	1.046
200	3175	1850	1733	1.068 ± 0.036	1.050
250	4022	2416	2109	1.146 ± 0.034	1.054

cars of the same mass but different wheelbase. As the criterion of equal mass is too restrictive, we consider immediately crashes between cars with masses the same to within some small amount and examine driver fatalities in the shorter wheelbase car compared with those in the longer wheelbase car.

The results for cars of model year 1979 or earlier (Table 2) show no hint of any dependence of fatality risk on wheelbase when the masses of the cars are similar. When the masses are within 20 kg of each other, the average wheelbase ratio is 1.044. If the relationship in Figure 3 reflected a pure influence of wheelbase ratio (rather than a surrogate for mass) on fatality risk, then substituting $\nu = 1.044$ should generate the observed driver fatality risk ratio. The computed value of 1.45 should be contrasted to the observed value (not different from 1). Recall that applying the corresponding calculation when the wheelbase was fixed led to reasonable agreement between predicted and observed fatality ratios. It is only when the masses differ by more than 150 kg that the fatality ratio begins to depart clearly from unity. This difference is interpreted as being due to the strong correlation between wheelbase and mass.

For cars of model year 1980 or later (Table 3), fatalities in the shorter car exceed those in the longer car for all mass differences tabulated. However, for no case when the masses are within 150 kg of each other does the difference approach any normally quoted level of statistical significance; indeed, as the sample sizes increase, the ratio of fatalities in the shorter car to those in the longer approaches closer to one until the effect of mass begins to influence strongly results at mass differences in excess of 200 kg. Substituting 1.043 into the relationship in Figure 4 computes a ratio of 1.33. None of the observed ratios comes close to such a value, again demonstrating that the relationship in Figure 4 is not showing the influence of size, but of mass.

The results in Tables 2 and 3 consistently show that when cars of similar mass but different wheelbase crash into each other, the wheelbase does not produce any clearly observable effect on driver fatality risk ratio.

Discussion

Examining crashes between cars with the same wheelbase provides definitive empirical evidence that mass is the main causative factor in the strong relationship between driver fatality risk and car mass in two-car crashes. The relationship between driver fatality risk and mass ratio when cars of equal or similar wheelbase crash into each other is quantitatively similar to the relationship with mass ratio when cars in general crash into each other, regardless of wheelbase. On the other hand, when cars of similar mass crash into each other, no effects dependent on wheelbase are found.

There are compelling physical reasons why increased car mass should reduce occupant risk in essentially all types of crashes. In the case of two-car crashes, the effect flows directly from Newton's

laws of motion, which require that when two objects collide, the speed change each undergoes is in inverse proportion to its mass. It is this speed change that generates the forces that lead to death and injury. Because the speed change decreases with increased mass by amounts unrelated to size or shape, increased car mass intrinsically provides increased protection to the occupants of a car when that car strikes another car, or any other vehicle, or any other object.

There is evidence that car size does play a role in two-car crashes. The strongest is that when cars of the same mass crash into each other, fatality and injury risk is lower for two heavier cars crashing into each other than for two lighter cars crashing into each other.[1,3,7,8] As the broad dynamical characteristics of a crash between two identical cars should not depend on their mass, the explanation of this finding would appear to be in terms of car size rather than mass, even though the relationships are reported in terms of mass. If one accepts the strongest relationship published (doubling the mass halves the risk), and the relationship between car mass and wheelbase derived here, then a 4% larger wheelbase would generate about a 10% lower driver fatality risk. This is just below the threshold of detectability, although such a difference is arguably a more harmonious interpretation of Table 3 than the equally defensible interpretation of no effect.

All the analyses in this paper have related fatality risk ratios to ratios of wheelbase or mass. These analyses in themselves cannot exclude the possibility that larger size in one involved car could generate equal proportionate risk reductions for both involved drivers, with no consequent effect on the fatality risk ratio. Based on the finding that the effect of mass is similar whether wheelbase is fixed or allowed to vary, and the much lesser magnitude of other effects that can be attributed to size, we consider such effects to be, at most, small compared with the large and unmistakable effect of mass. We consider that car size analyses that focus on car mass,[2,3] are focusing on the single variable that best captures most, but certainly not all, of the safety changes that occur as a function of changing vehicle size.

The conclusion that size has no more than a small influence on fatality risk in two-car crashes suggests that size may have a correspondingly small effect on injury outcome (as distinct from crash involvement) in single-car crashes. If so, then a substantial portion of relationships between driver fatality risk and car mass in single-car crashes[1,11] may likewise be due to mass, as such. Conceptually, the role of mass in single-car crashes has often been misunderstood because barrier crash tests so often come to mind as representing single-car crashes. A barrier crash test is so inadequate a representation of real-world crashes that it is not surprising that no relationship between barrier crash test performance and real-world performance has ever been reliably observed. Unlike the nominal design features of the barrier, the average object struck in the real world is not infinitely stiff, infinitely massive, or infinitely unbreakable.

In any large set of crashes, many of the objects struck by vehicles will move, dent, deform, or tear. Each of these effects reduces forces on occupants. The heavier the striking vehicle, other factors being equal, the more likely is a struck object (such as a tree, the most common fixed object in fatal crashes) to break. If the vehicle breaks or uproots the tree, rather than bouncing back from it, risk to occupants is dramatically reduced. Even the proverbial brick wall from which a light car will bounce back may still be penetrated by a heavier vehicle, with beneficial effects to its occupants. Observed relationships between car-driver risk in car–truck crashes[2,11] may arise in part because increased car mass will, on average, produce greater damage to the impacted area of the truck, with consequent reductions in the forces on the car driver.

Risks in single-car crashes, two-car crashes, and crashes between cars and other vehicles all increase with decreasing car mass. Many of the mechanisms flow from the most basic physical laws involving mass in dynamical equations, whereas others, such as substantially higher rollover crash risk in lighter cars, flow from the close relationship between car mass and car size. All effects combine to generate a strong relationship between overall risk and car mass. It is not surprising that all of the many studies performed using credible methodologies have found large relationships between overall risk and car mass. A recent claim[12] that mass is unimportant seems just one more example of "the triumph of zeal over science, or perhaps even common sense"[1(p83)]; a few regression parameters backed up by no raw data are presented to support this claim, which implies that all prior work is incorrect and that cars do not obey the laws of physics after all.

TABLE 3—Crashes between Cars of Similar Mass: Examination of the Influence of Wheelbase for Cars of Model Year 1980 or Later

Maximum Difference between Car Masses, kg	No. of Crashes	Fatalities in: Shorter Car	Fatalities in: Longer Car	Ratio ± SE	$\bar{v}$
20	166	98	87	1.126 ± 0.166	1.043
30	246	144	128	1.125 ± 0.137	1.042
40	326	183	175	1.103 ± 0.115	1.042
50	405	239	212	1.127 ± 0.106	1.041
70	575	327	310	1.055 ± 0.084	1.042
100	831	470	456	1.031 ± 0.068	1.042
150	1236	706	672	1.051 ± 0.057	1.045
200	1642	949	876	1.083 ± 0.051	1.048
250	2053	1223	1054	1.160 ± 0.049	1.051

Conclusions

As a result of this study, we made the following conclusions: First, when cars of similar wheelbase but different mass crash into each other, driver fatality risk is higher in the lighter car. The large difference agrees quantitatively with predictions of relations derived only in terms of mass, without considering wheelbase. Second, when cars of similar mass but different wheelbase crash into each other, driver fatality risk in the shorter and longer wheelbase cars are similar. Finally, mass is the dominant causative factor in the large dependence of driver fatality risk on mass in two-car crashes, with size playing at most a secondary role. □

Call for Abstracts for Epidemiology Late-Breaker Sessions

Exchange Session

The Epidemiology Section will sponsor a "late-breaker" Epidemiology exchange on Wednesday, November 11, 1992, during APHA's 1992 annual meeting in Washington, DC. The exchange will provide a forum for presentation of investigations or methods that have been conceived, conducted, and/or concluded so recently that members could not meet the deadline for abstract submission to other Epidemiology sessions. Abstracts should report on work conducted during the last 6–12 months.

Abstracts of fewer than 200 words (any format) and a stamped, self-addressed return envelope should be submitted to Polly A. Marchbanks, PhD, Chief, EIS Program, Epidemiology Program Office, Mailstop C08, Centers for Disease Control, Atlanta, GA 30333; (404) 639-3588.

Abstracts must be *received* by September 28, 1992. Decisions will be made by October 5, 1992.

Poster Session

The Epidemiology Section will again be sponsoring a late-breaker poster session at the annual meeting. The session will take place on Wednesday, November 11, 1992. Work completed in 1992 is eligible for consideration. Submit an abstract of fewer than 200 words (any format) and a *return envelope* to Cathey Falvo, MD, MPH, Graduate School of Health Science, Munger Pavilion, New York Medical College, Valhalla, NY 10595; tel. (914) 993-4323.

Abstracts must be *received* by October 2, 1992. Decisions will be mailed October 5, 1992. Students and recent graduates are particularly encouraged to submit abstracts.

The Development of Registries for Surveillance of Adult Lead Exposure, 1981 to 1992

Michael E. Baser, PhD

ABSTRACT

Objectives. Since 1981, 15 states have established registries for surveillance of adult lead absorption, primarily based on reports of elevated blood lead levels from clinical laboratories. I review the status of the registries and recommend steps for further development.

Methods. Companies reported to the New York registry are compared with those cited by the Occupational Safety and Health Administration (OSHA). I present data on US workers and plants with potential lead exposures and blood tests, as well as review registries' reporting requirements.

Results. Registries identify many companies not cited by the Occupational Safety and Health Administration, but underreporting occurs because (1) reporting is usually not required from laboratories outside the state, (2) most registries use a blood lead reporting level of 1.21 μmol/L, which excludes many exposed workers, and (3) many companies with potential exposures do not have routine monitoring programs.

Conclusions. Registries' reporting requirements and procedures should be standardized, including a blood lead reporting level of 0.72 μmol/L. Elevated blood lead levels should be a reportable condition nationwide, and a comprehensive national surveillance system should be established: clinical laboratories should be required to report cases to those states with lead registries or directly to the national adult lead registry. (*Am J Public Health.* 1992;82:1113–1118)

Introduction

Lead adversely affects the hematologic, central and peripheral nervous, cardiovascular, renal, and reproductive systems.[1] A variety of surveillance methods have been proposed to identify, first, morbidity and mortality potentially associated with lead exposures and, second, companies or workers with lead exposures.[2–7] The National Occupational Exposure Survey (NOES),[8] conducted from 1981 to 1983, estimated that almost 1.4 million workers were exposed to inorganic lead or lead compounds (Table 1). Many industries have airborne lead concentrations greater than the permissible exposure limit (PEL) set by the Occupational Safety and Health Administration (OSHA), which is 50 $\mu g/m^3$ averaged over an 8-hour work shift.[9,10] Furthermore, the prevalence and severity of exposures in a number of industries with high lead exposures have not declined in recent years.[10]

The OSHA lead standard requires that companies provide industrial hygiene and medical surveillance programs (including measurement of blood lead levels) when airborne lead concentrations exceed 30 $\mu g/m^3$ averaged over an 8-hour work shift.[9] A worker must be removed from exposure if (1) the mean blood lead level of the worker's last three tests, or the mean of all of the worker's tests over the previous 6 months, is greater than or equal to 2.42 μmol/L (1 μmol/L = 20.72 μg/dL); or (2) any test is greater than or equal to 2.90 μmol/L; or (3) the worker's medical condition contraindicates continued lead exposure.

Methods and Results

In 1981, the New York State Health Department began population surveillance of adult lead exposure, using blood lead results from industrial medical surveillance programs and other sources.[7] State statutes require clinical laboratories, employers, and health facilities to report individuals with elevated levels of heavy metals in blood and urine samples. State agencies provide follow-up, which includes education for employers, workers, and clinicians, industrial hygiene evaluations, and medical consultation.

Adult lead registries have been established in 15 states, primarily based on reporting from clinical laboratories (Table 2). Through 1990, the New York registry had received reports on 4735 workers from 695 companies or work sites; the New Jersey registry, 2851 workers from 271 companies; the California registry, 2779 workers from 250 companies;[11] and the Texas registry, 1116 workers from 101 companies. Many of these companies had employees with markedly elevated blood lead levels. Of the 695 work sites reported to the New York registry, 197 (28.3%) had at least one employee with blood lead levels exceeding the OSHA medical removal protection levels. These included 15 of 34 heavy construction companies (44.1%; Standard Industrial Classification[12] [SIC] 16), 27 of 61 special trade contractors (44.3%; SIC 17), 22 of 43 primary metal industries (51.2%; SIC 33), 17 of 32 fabricated metal product companies (53.1%; SIC 34), 13 of 25 scrap

[a]Inorganic lead in lead ore, lead compounds/complexes, lead alloys, and lead in welding, brazing, and soldering. An estimated 222 207 ± 22 221 workers were exposed to organolead compounds.

[b]Potential or inferred exposure is annual average exposure ≥ 30 minutes/week, or usage ≥ once/week for 90% of weeks/year.

[c]"Blood tests" is an affirmative answer to the question of blood tests provided to selected or all employees, with the exception of tests provided only to executive or management employees. The question does not specifically refer to lead.

[d] ... = not available. SEs were estimated using coefficients based on a nonlinear regression of 792 SEs for different-sized estimates from 44 SIC groups; at present, SEs cannot be estimated for zero values or for percentages.

and waste material companies (52.0%; SIC 5093), and 20 of 84 automotive repair shops (23.8%; SIC 7539).

Although many workers and companies are reported to registries, registries underestimate the prevalence of occupational lead exposure because only a small fraction of companies with potential lead exposures perform routine biological monitoring. A survey of California lead-using companies estimated that only 2.6% ever performed environmental monitoring and only 1.4% had routine biological monitoring.[13] Using different methods in a national sample,[8] the NOES estimated that 11.8% of companies with potential inorganic lead exposures had blood tests performed on employees (Table 1). The prevalence of routine biological monitoring is especially low in small companies and the construction industry,[8,13,14] which has a permissible exposure limit of 200 $\mu g/m^3$ and no OSHA requirements for routine air or blood sampling.[15] The NOES estimated that only 0.1% of 198 790 lead-exposed construction workers received blood tests and that there were no blood tests for exposed workers in oil and gas extraction (SIC 13), auto repair, services, and garages (SIC 75), and miscellaneous repair services (SIC 76).

Lead registries complement OSHA inspections in two ways. First, registries detect many companies not cited by OSHA,[7,16] whose inspection program focuses on larger manufacturing companies with well-recognized lead hazards. Through 1990, only 76 of the 695 work sites (10.9%) reported to the New York registry were also cited by OSHA. These included 62 of 187 manufacturing companies (33.2%) but only 14 of 508 nonmanufacturing companies (2.8%) ($P < .001$, chi-square test). Second, registry data and OSHA inspection results can be used to target interventions because companies detected by both methods have particularly high exposures.[12] Through 1990, 580 New York companies were cited by OSHA for violations of the federal lead standard. Of 76 cited companies that were also reported to the New York registry, 49 (64.5%) were cited for airborne lead concentrations above the permissible exposure limit, compared with 70 of 504 companies (13.9%) cited by OSHA but not reported to the registry ($P < .001$, chi-square test).

Recommendations for Registry Development

The reporting requirements and procedures vary among states (Table 2) and should be standardized to ensure wider and more uniform reporting and a common basis for interventions and data comparisons.

1. *Blood lead reporting level.* A level of 0.72 μmol/L or lower should be adopted, as four states have done. The probability of detecting excessive expo-

sures is related to the frequency of exposure measurement.[17] Because many companies with lead exposures do not have biological monitoring programs, a relatively low blood lead level that is incidentally reported to a registry can be indicative of higher exposures.

Most states currently have a blood lead reporting level of 1.21 μmol/L, and the number of reported cases will increase if the reporting level is set at 0.72 μmol/L. For example, 49% of the workers reported to the Alabama registry in 1991 had initial blood lead levels from 0.72 to 1.20 μmol/L. Additional personnel should be provided to ensure adequate follow-up.

2. *Other information on lead exposures.* To augment reporting based on blood lead levels, registries should reference information on lead-using companies, OSHA inspection results, and workers' compensation claims.[7,13,16,18] Some registries estimate the prevalence of elevated lead absorption by determining the

number of potentially exposed workers, using a questionnaire; the California questionnaire is a good model. The Iowa registry requires the reporting of the results of all blood tests. Work histories should be elicited from workers aged 15 and older, in order to include those who leave school before age 18 and students with summer or part-time jobs.

3. *Other heavy metals.* Increased absorption of mercury, arsenic, and cadmium should be reported. Through 1990, the New York registry received reports on 1505 mercury cases from 70 companies (including many workers from a chlor-alkali plant), 151 arsenic cases from 22 companies, and 63 cadmium cases from 18 companies.

4. *Response time.* To expedite follow-up in the most serious cases, blood lead levels above 2.42 μmol/L (the OSHA biological limit value) should be reported within 24 hours. Through 1990, only 24.7% of New York tests above 2.42 μmol/L were reported within 10 days and 63.7% within 30 days; only 19.1% of all tests were reported within 10 days, the statutory requirement. In 1987, only 9% of California tests were reported within 3 days.[19]

5. *Reporting sources.* Clinicians are required by many states to report lead or heavy metals poisoning[20] and should also report directly to registries. In practice, employers, health facilities, and clinicians send samples to laboratories, which then send the results to registries. In New York, through 1990 93.4% of workers and 95.9% of companies have been reported by laboratories, alone or jointly with other sources. Laboratories should be audited to ensure that all cases have been reported, as the New York registry has done.

6. *Location of reporting sources.* Reporting should be sought from out-of-state laboratories because clinical laboratories do not have strictly local clients. Of the 15 state registries, only New York requires reporting from all laboratories that analyze blood from state residents. Thirty-three of the 72 laboratories reporting to the New York registry are located outside the state; through 1990, 80.5% of workers and 77.0% of companies have been reported from these laboratories. An estimated 47% of blood lead samples from biological monitoring programs in California are analyzed by laboratories outside the state.[13]

Several methods can be used to broaden reporting from clinical laboratories. All states should designate elevated blood lead levels as a reportable condition and, as in New York, should use or create licensing authority to require reporting from both in-state and out-of-state laboratories. Alternatively, federal legislation could be enacted for these purposes. Blood lead levels from residents of states without registries should be reported directly to the national adult lead registry, which could then share the data with state health and labor departments. The national registry, at the Centers for Disease Control's National Institute for Occupational Safety and Health (CDC-NIOSH), uses data from existing registries (Table 2).

7. *Identification of laboratories.* Commercial, public health, and university hospital laboratories that analyze lead in childhood and adult blood samples can be identified in several ways. Some laboratories participate in proficiency testing programs operated by the College of American Pathologists (about 300 laboratories), the CDC (about 200 laboratories), and the state health departments of New York and Pennsylvania (about 70 laboratories each). About 250 of these laboratories ask the OSHA Salt Lake Technical Center to determine whether their performance meets OSHA requirements for biological monitoring.

The principal laboratories that test for lead and other toxins in biological samples can also be identified from a national survey by the Health Care Financing Administration. The survey is being conducted to support the Clinical Laboratory Improvement Amendments (CLIA) of 1988, which require certification for laboratories that test human materials for diagnosis or treatment.[21] It is expected that 200 000 to 250 000 facilities will be identified from the 640 000 potential facilities to which questionnaires have been sent. The questionnaire includes the number, type, and methodology of laboratory procedures and the qualifications of the supervisors and technicians. The CLIA also require certification for noncommercial laboratories (e.g., those operated within manufacturing industries), but these laboratories are not included in the survey.

Conclusion

New methods and additional resources are needed to achieve the national health objective of eliminating occupational lead exposures resulting in blood lead levels above 1.21 μmol/L.[1,22] Adult lead registries complement other forms of surveillance in identifying companies with excessive lead exposures. Reporting requirements and procedures should be standardized. Elevated blood lead levels should be a reportable condition nationwide, and a comprehensive national surveillance system should be established: clinical laboratories, regardless of location, should report cases to states with adult lead registries or, with those cases from states without registries, directly to the CDC-NIOSH registry. □

Call for Abstracts for Injury Control/Emergency Services Late-Breaker Session

The Injury Control and Emergency Health Services Section will again sponsor a "late-breaker" session during the APHA 1992 annual meeting in Washington, DC. The session will be held on Tuesday, November 10, and will feature work completed within the last few months (after the deadline for consideration in the regular symposia of the APHA annual meeting).

Submit abstracts of 250 words or fewer (any format) and a return envelope to Richard Waxweiler, Division of Injury Control, Centers for Disease Control, Mail Stop F-36, Atlanta, GA 30333; tel. (404) 488-4690.

Abstracts must be received by September 1, 1992. Decisions will be made by September 15, 1992.

Lower Respiratory Illness in Infants and Low Socioeconomic Status

Peter A. Margolis, MD, PhD, Robert A. Greenberg, MD, MSPH, Lynette L. Keyes, MS, MPH, Lisa M. LaVange, PhD, Robert S. Chapman, MD, MPH, Floyd W. Denny, MD, Karl E. Bauman, PhD, and Barbara W. Boat, PhD

ABSTRACT

Objectives. Infants from families of low socioeconomic status are said to suffer higher rates of lower respiratory illness, but this assertion has not been carefully examined.

Methods. We studied the frequency and determinants of lower respiratory illness in infants of different socioeconomic status (n = 393) by analyzing data from a community-based cohort study of respiratory illness during the first year of life in central North Carolina.

Results. The incidence of lower respiratory illness was 1.41 in the low socioeconomic group, 1.26 in the middle group, and 0.67 in the high group. The prevalence of persistent respiratory symptoms was 39% in infants in the low socioeconomic group, 24% in infants in the middle group, and 14% in infants in the high group. The odds of persistent respiratory symptoms in infants of low and middle socioeconomic status were reduced after controlling for environmental risk factors for lower respiratory illness. Enrollment in day care was associated with an increased risk of persistent symptoms among infants of high but not low socioeconomic status.

Conclusions. Infants of low socioeconomic status are at increased risk of persistent respiratory symptoms. This risk can be partly attributed to environmental exposures, most of which could be changed. (*Am J Public Health.* 1992;82:1119–1126)

Introduction

Lower respiratory illnesses are major causes of childhood morbidity in the United States. Approximately 30% of infants less than 1 year of age visit a doctor for a lower respiratory illness, and about 1% of infants who are healthy at birth are hospitalized for the illness.[1–6] Although the vast majority of acute lower respiratory illnesses are without complication, recent studies indicate that the occurrence of these illnesses in infancy may predispose to the development of obstructive airways disease in later life.[7–9]

Clinical experience suggests that infants of low socioeconomic status have higher rates of lower respiratory illness than more socially advantaged infants, but few studies have investigated this relationship. Previous studies of socioeconomic status and lower respiratory illness have provided limited information because they have examined only differences in mortality rates or because they have been hospital rather than community based.[5,6,10] The major studies of respiratory illness in childhood have focused on lower respiratory illness in middle-class families or on upper respiratory illness.[11,12] Thus, it is unclear whether the clinical impression that infants of low socioeconomic status have higher rates of lower respiratory illness is correct, and if so, whether it reflects an increased incidence of this illness, more severe illness, or more chronic illness.

The objectives of this study were to determine whether rates of acute lower respiratory illness and chronic respiratory symptoms differ among socioeconomic status groups and to identify environmental risk factors that might account for whatever differences in rates of disease were observed and that might be amenable to clinical or public health intervention.

Methods

Study Sample

We analyzed data from the control group of a community-based randomized trial designed to study the effects of an intervention to reduce infants' exposure to tobacco smoke and, thereby, their rate of lower respiratory illness in the first year of life. In the trial, an attempt was made to enroll a large proportion of the infants born in Alamance and Chatham counties in central North Carolina between 1986 and 1988. Recruitment of families took place at three hospitals at which 80% of the births in these counties occur. All mothers who gave birth to infants who weighed more than 2000 g and who did not require neonatal care outside the normal newborn nursery were asked to participate. At the time of recruitment, families

This paper was submitted to the Journal July 16, 1991, and accepted with revisions December 10, 1991.

were told only that the study was intended to investigate infant health during the first year of life.

Data about potential risk factors for lower respiratory illness were collected during home interviews when the infants were 3 weeks and 12 months of age. Information was elicited by questionnaires administered to the infants' mothers and included demographic, environmental, and psychosocial characteristics. Data collectors were not told the objectives of the study.

Measurement of Respiratory Illness

We used two measures of respiratory illness: acute lower respiratory illness and persistent respiratory symptoms.

Symptoms of acute lower respiratory illness were measured by telephone calls to the families every 2 weeks. Telephone interviewers used standardized data collection forms and inquired about respiratory as well as nonrespiratory symptoms. Only the families with telephones, who constituted 85% of the study sample, were questioned about the presence of acute symptoms.

Acute lower respiratory illness was defined as the parents' report of the presence of cough, wheezing, and rattling in the chest. The incidence of acute lower respiratory illness was expressed as the number of episodes per child year at risk. The choice of this definition was based on a separate study of patients from the University of North Carolina Hospitals outpatient department and a private pediatric practice.[13] In this study, the combination of symptoms of cough plus wheezing and rattling in the chest had a sensitivity of 88% (95% CI = 0.80, 0.96) and a specificity of 68% (95% CI = 0.60, 0.76) in identifying lower respiratory illness (likelihood ratio = 2.75; 95% CI = 2.07, 3.65).

The presence of persistent respiratory symptoms was measured at the 12-month home interview using the American Thoracic Society children's questionnaire for studies of respiratory illness.[14] The questionnaire was modified slightly to make it more appropriate for use with infants. Infants who were reported to "usually cough" or "occasionally wheeze" were classified as having persistent respiratory symptoms. All families in the study were asked about the presence of persistent symptoms, regardless of whether they had telephones.

Measurement of Risk Factors for Respiratory Illness

The infants' socioeconomic status was classified into three levels according to the highest level of education achieved by the head of the household. Families in which the head of the household did not graduate from high school were classified as low socioeconomic status. If the head of household had completed only high school, the family was placed in the middle socioeconomic group; if more than a high school education, the high group. We used educational achievement because it appears to be a relatively stable measure of socioeconomic status in young families, whose incomes or occupational status may be increasing. Education is also the socioeconomic status measure that is most closely associated with health outcomes in children.[15,16]

Each infant's exposure to tobacco smoke was measured as the number of cigarettes smoked in the infant's presence during the week prior to the 12-month home visit. We chose to measure exposure at the 12-month home visit because other evidence from this study indicated that the amount of exposure remained stable throughout the entire first year of life.[17] In these analyses, infants were considered exposed to tobacco smoke if any smoking occurred in their presence during this time period. The questionnaire that was used for this measurement is described in detail elsewhere.[18]

Infants were considered exposed to day care if they were with at least one other child who was not their sibling for more than 4 hours per week and if they were cared for by someone other than their parents.[19,20] Day-care exposure was measured at the 12-month home interview. Household crowding was defined as the number of persons per room in the house and was classified into three levels: less than 0.5 persons per room, 0.5 through 1.0 persons per room, or more than 1.0 persons per room. Infants were considered exposed to smoke from a wood stove if the wood stove was the primary source of home heating.

Feeding and stress were measured at the 3-week home interview. Infants were classified as bottle fed if they received only formula and as breast fed if they received human milk with or without formula. Mothers' psychological stress was measured at the first home interview by seven questions from the Rand Mental Health Inventory.[21] The scores on the individual questions were averaged to provide a summary measure of stress. The summary measure was grouped into tertiles to define low, medium, and high levels of stress. We used this grouping to increase the clinical interpretability of our results.

A family history of allergy was defined as the presence of asthma or hay fever in either parent. The season of an infant's birth was considered to be respiratory if the infant was born between October and March and nonrespiratory if the infant was born between April and September.[22]

Statistical Analyses

The variance of the incidence density of lower respiratory illness was computed using the Taylor series method.[23] The significance of the differences in incidence of lower respiratory illness across socioeconomic status groups was assessed by a test for linear trend using a Wald χ^2 statistic.[24]

Relationships between the respiratory risk factors, socioeconomic status, and persistent respiratory symptoms were summarized by prevalence relative risks, and statistical significance was assessed by χ^2 tests. After calculating the unadjusted relative risk of persistent respiratory symptoms for the low and middle socioeconomic groups compared with the high socioeconomic group, Cochran-Mantel-Haenzel methods were used to adjust the relative risk estimates and confidence intervals for the effects of individual risk factors.[25]

We used logistic regression to analyze to what extent the relationship between socioeconomic status and persistent respiratory symptoms could be accounted for by simultaneously considering interactions between socioeconomic status and other risk factors for lower respiratory illness and confounding by other risk factors.[26,27] In the models, only the risk factors associated with both the presence of persistent symptoms and socioeconomic status were considered.[27] The predictor variables in the full model were examined for evidence of collinearity using standard analysis techniques.[28] Crowding, stress, and socioeconomic status were included in the logistic models as interval variables after plots confirmed that each had a linear relationship with the outcome variable on a logit scale.[29]

To determine whether effect modification was present, the full model, which included all two-way interactions between the risk factors and socioeconomic status, was simplified by deleting statistically

nonsignificant interactions in a backward selection procedure (maximum likelihood χ^2 statistic; P value = .1 to remain in the model). Only two-way interaction terms were considered for inclusion in the models, and the sole significant interaction was between socioeconomic status and day care. After assessing for effect modification, we determined whether any of the risk factors could be removed from the model including the socioeconomic status and day-care interaction without an important change in the estimated effect of socioeconomic status.[27] The final model was used to estimate the prevalence of persistent symptoms for groups of infants given various risk factors.[25]

Results

Characteristics of Study Participants

There were 2332 births in which the infant was eligible to participate in the intervention trial. Of the eligible families, 1091 (47%) agreed to enroll. Of the 516 infants who were randomized to the control group, 396 (77%) completed the study and were included in the analysis for this paper. Three infants were excluded because their race was neither White nor Black. The socioeconomic status of the 393 infants studied was as follows: 20% low, 31% middle, and 49% high.

Compared with the 1241 infants from families refusing enrollment, study infants were more likely to be of high socioeconomic status and were more often Black (Table 1). Study infants were less likely to have mothers who smoked. In families in which mothers did smoke, however, study mothers and mothers from families refusing enrollment smoked the same average number of cigarettes per day. The 33 families without telephones, for whom we do not have a measurement of the incidence of acute lower respiratory illness, were more often of low or middle socioeconomic status than those in the study group as a whole. The distribution of socioeconomic status among those without telephones was as follows: 49% low, 42% middle, and 9% high. However, the distribution of other risk factors in these groups appeared similar to the distribution of risk factors in the entire sample.

When compared with the infants of the 120 families who enrolled but did not complete the study, infants of families who completed the study were more often of high socioeconomic status (49% vs 20%) but less often Black (30% vs 47%) and less likely to have mothers who smoked (21% vs 37%). The distribution among socioeconomic groups of potential risk factors for lower respiratory illness (household crowding, exposure to tobacco smoke) was the same among study infants and dropouts.

Frequency of Respiratory Illness

Both the incidence of acute lower respiratory illness and the prevalence of persistent symptoms had dose-response relationships with socioeconomic status. The incidence of acute lower respiratory illness (episodes per child year) was 1.41 for low socioeconomic infants, 1.26 for middle socioeconomic infants, and 0.67 for high socioeconomic infants (P = .009 for linear trend). The relationship between the prevalence of persistent respiratory symptoms and socioeconomic status was even more marked (Table 2). Among in-

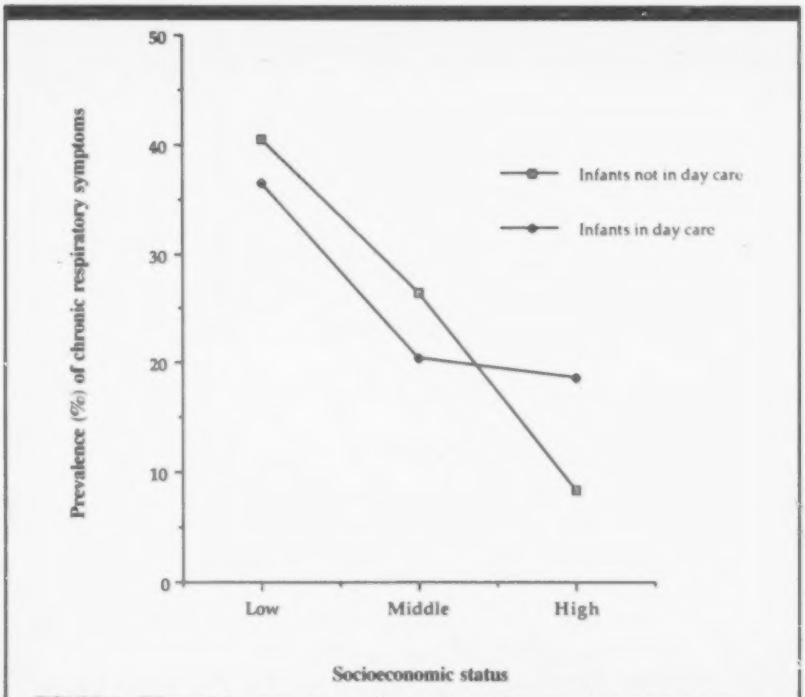

FIGURE 1—Effect of day care on prevalence of persistent respiratory symptoms.

fants of low socioeconomic status, 39% had persistent symptoms; only 14% had persistent symptoms in the high socioeconomic group. Infants in the low socioeconomic group were 2.9 (95% CI = 1.9, 4.5) times more likely than infants of high socioeconomic status to have persistent respiratory symptoms.

Infants who had persistent respiratory symptoms were more likely to have had an acute lower respiratory illness than those who did not have persistent symptoms. Of infants with persistent symptoms, 68% had at least one episode of acute lower respiratory illness, whereas only 32% of infants without persistent symptoms had any episodes of the illness ($P < .0001$, χ^2). However, the presence of persistent symptoms did not represent repeated episodes of acute lower respiratory illness. Among infants with persistent symptoms who had experienced an acute lower respiratory illness, most (63%) had only one or two episodes, and only 15% had more than three episodes.

Relationship of Risk Factors to Socioeconomic Status and Persistent Respiratory Symptoms

To investigate how much of the effect of socioeconomic status could be related to demographic, environmental, or psychosocial factors, we evaluated its association with persistent respiratory symptoms after controlling for risk factors for lower respiratory illness[30–37] that were also associated with both socioeconomic status and persistent respiratory symptoms in our data. We focused on persistent or continuing respiratory symptoms because they may be indicative of the long-term impact of acute respiratory illness. In these analyses, factors that contributed to the effect of socioeconomic status would lead to a decrease in the association between socioeconomic status and persistent respiratory symptoms.

Table 3 shows the relationship of the risk factors we studied to socioeconomic status, and Table 4 indicates their relationship to persistent respiratory symptoms. Of the demographic, familial, and environmental factors, only the infants' sex and season of birth were not associated with socioeconomic status. Although the association of low birthweight with persistent symptoms was not statistically significant ($P = .074$), the prevalence of this risk factor in the study sample was low (4.6%) because infants weighing less than 2000 g were excluded from the study. We decided to adjust for low birthweight in studying the relationship between socioeconomic status and persistent symptoms, however, because the magnitude of its relationship was clinically relevant (relative risk = 1.85) and because there was previous evidence of its association with persistent respiratory illness.[38] Thus, household crowding, exposure to tobacco smoke, style of feeding, birthweight, stress, and race were related to both socioeconomic status and persistent respiratory symptoms.

The effect of day care on persistent symptoms differed significantly according to the socioeconomic status of the infant (Figure 1). Among infants of high socioeconomic status, enrollment in day care was associated with an increase in the prevalence of persistent symptoms. In infants of low and middle socioeconomic status, however, enrollment in day care was associated with a reduction in the prevalence of persistent symptoms.

Effect of Risk Factors on the Relationship of Socioeconomic Status to Persistent Respiratory Symptoms

To evaluate the effect of the risk factors on the relationship between socioeconomic status and persistent respiratory symptoms, we compared the unadjusted relative risk of persistent symptoms in the low and middle socioeconomic groups with the relative risk of persistent symptoms after adjusting for each risk factor separately by stratified analysis (Table 5). The greatest reduction in the relative risk occurred after control for exposure to household crowding and tobacco smoke among infants of low socioeconomic status. Control for crowding decreased the relative risk among infants of low compared with high socioeconomic status from 2.9 to 2.2, and control for tobacco smoke exposure reduced the relative risk of persistent symptoms to 2.3.

We used logistic regression to evaluate how much of the effect of socioeconomic status on persistent symptoms might be produced by all the risk factors together. We compared the odds of persistent symptoms in a model that did not adjust for the effect of the risk factors with the odds of persistent symptoms in a model that adjusted for all the risk factors together (see Appendix). The odds ratios estimated from the models do not approximate the relative risks calculated by stratified analysis because of the high prevalence of persistent symptoms.

In the model that did not adjust for the effect of the risk factors, the odds ratio of persistent symptoms among infants of low compared with high socioeconomic status was 12.4 (95% CI = 7.5, 20.3) for those not in day care (Table 6). Among infants in day care, the odds ratio of persistent symptoms was 2.8 (95% CI = 1.6, 4.8). Control for all the risk factors reduced the odds of persistent symptoms among infants of low compared with high socioeconomic status from 12.4 to 6.9 (95% CI = 3.8, 12.2) for infants not in day care and from 2.8 to 1.3 (95% CI = 0.7, 2.4) for infants in day care. After accounting for all the risk factors, the effect of socioeconomic status remained significant only for infants not in day care.

To illustrate how much these risk factors contributed to the effect of socioeconomic status on persistent symptoms, we estimated the prevalences of persistent respiratory symptoms from the logistic model for infants of different socioeconomic status groups who were exposed to

[a]Risk factors: crowding, tobacco smoke, bottle feeding, low birthweight, stress, Black race.

various risk factors. Tables 7 and 8 show the estimated effect of the risk factors among infants in day care (44% of the sample) and not in day care. For example, for infants of low socioeconomic status not in day care (Table 7) and not exposed to any risk factors, the prevalence of persistent symptoms would be about 22%. Exposure to tobacco smoke would increase the prevalence of persistent symptoms to 28%; crowding and smoking to 59%. Exposure to all the risk factors would increase the prevalence of persistent symptoms to 80%. Although these risk factors increased the probability of persistent respiratory symptoms in all socioeconomic groups, the effect of the risk factors on the prevalence of symptoms would be greatest in the low socioeconomic group. Among infants of low socioeconomic status, the difference in prevalence between those exposed to all the risk factors and those exposed to none would be 58%. Among infants of high socioeconomic status, however, the difference would be only 33%. For infants who were enrolled in day care, the effects of exposure to risk factors were similar in all three socioeconomic groups (Table 8).

Discussion

Our results indicate that infants of low socioeconomic status experience a higher incidence of acute lower respiratory illness and a higher prevalence of persistent respiratory symptoms than infants of high socioeconomic status. These results could have occurred if families of low socioeconomic background were more likely to report symptoms in their children. However, there is evidence that highly educated families are more likely than less-educated families to report respiratory symptoms.[39] In our assessment of the validity of our acute respiratory symptoms questionnaire, we did not detect clinically or statistically significant differences by socioeconomic status in responses to the questions, but our sample was small.

The differences we observed in the frequencies of respiratory symptoms across socioeconomic strata are also not explained by how we measured respiratory illness. Inaccuracy in the measurement of acute lower respiratory illness and persistent respiratory symptoms would have led to random misclassification of respiratory illness and diminished the observed differences between socioeconomic groups. Therefore, the effects of socioeconomic status we found are likely to be conservative estimates.

The large number of infants who were not in the study sample may limit the generalizability of our results. Only about half of the eligible families were enrolled in our study, and there were some differences in the distribution of risk factors and socioeconomic status between the study population and the target population. For example, infants in the study sample were of higher socioeconomic status, and fewer had mothers who smoked. This exposure to fewer risk factors among study infants compared with the population as a whole also indicates that our results may represent conservative estimates of the differences between socioeconomic groups.

Although socioeconomic status affects both the incidence of acute lower respiratory illness and the prevalence of persistent respiratory symptoms, its impact appears to be greater on the prevalence of persistent symptoms. One possible explanation for the differing effects of socioeconomic status on acute lower respiratory illness and persistent symptoms may be that factors related to socioeconomic status have a more pronounced effect on infants' risk of developing serious or chronic lower respiratory illness than on their risk of becoming infected. This explanation is consistent with the results of other studies that indicate that socioeconomic status appears to have little effect on rates of upper respiratory illness, but more of an effect on acute lower respiratory illness and a still greater influence on serious and chronic forms of this illness.[12,40]

There are insufficient data to assess the long-term clinical significance of persistent respiratory symptoms in 1-year-old infants. In studies of older children, however, a history of chronic cough and occasional wheezing has been associated with decrements in measurements of pulmonary function,[41] and such reduced ventilatory function may be associated with chronic obstructive airways disease.[7]

There is little direct information about differences in incidence of acute lower respiratory illness across socioeconomic groups. However, the one previous study of this question found differences in incidence rates that were similar to ours. Gardner et al.[42] described the incidence of lower respiratory illness in 23 low socioeconomic infants and 48 high socioeconomic infants who were participants in a community viral surveillance project in Houston. Lower respiratory illness was diagnosed by physical examination at home visits every 1 to 2 weeks. Although we used a telephone survey to identify illnesses in a larger and community-based cohort identified at birth, the incidence rates of lower respiratory illness they observed (1.43 episodes per child year in the low socioeconomic group, 1.0 episodes per child year in the middle socioeconomic group, and 0.72 episodes per child year in the high socioeconomic group) were similar to ours.

Previous evidence suggests that there are large differences in the severity of lower respiratory illness in infants of low compared with high socioeconomic status. For example, infants of low socioeconomic status who are healthy at birth have mortality rates from lower respiratory illness in the first year of life that are 2 to 4 times higher than those found among more advantaged children,[10,43] and other studies of infants suggest that hospitalization rates for lower respiratory illness are 5 to 10 times higher among poor as compared with middle-class infants.[5,44]

Chronic respiratory symptoms, too, are more prevalent in school-aged children of low socioeconomic status, but the effects of socioeconomic status on chronic respiratory symptoms in infancy have not been studied longitudinally. For example, Colley and Reid found the prevalence of chronic cough to be about three times higher in school children of low compared with high socioeconomic status.[45] Studies by Ware et al. and Schenker et al. also found that chronic cough and a history of serious "chest illness" in infancy were more common in children of low socioeconomic status.[46,47]

Of the risk factors for respiratory illness we found to be important in our study, most are supported by previous work.[30-37] The finding that day care was associated with a somewhat reduced prevalence of persistent symptoms in low socioeconomic families and an increased prevalence in high socioeconomic families was unexpected and has not been previously reported. It deserves exploration in another study. It is possible that the protective effect of day care among the infants of low and middle socioeconomic status could be related to the smaller size of their day-care groups or to a reduction in these infants' exposure to environmental factors such as tobacco smoke.[48] We found that families of low socioeconomic status tended to use day care less often and that infants in these families were more often cared for alone or in small groups (< 5 children), whereas infants of high socioeconomic status were more

commonly in large-group day-care settings in which the likelihood of exposure to infection is greater.

Our results indicate that much of the effect of socioeconomic status can be explained by factors that are related to the infant's home environment, most of which are mutable (exposure to tobacco smoke, crowding, stress, low birthweight, and bottle feeding). In addition, exposure to risk factors for respiratory illness is not only more common among families of low socioeconomic status, but the effect of the exposure also seems to be the greatest in this group, at least among infants not in day care. From a public health perspective, these findings indicate that infants of low socioeconomic status are especially likely to benefit from interventions that reduce their exposure to risk factors for respiratory illness. Given the high prevalence of persistent symptoms in infants of low socioeconomic status, even small changes in what are potentially mutable environmental risk factors could have a substantial impact on the health of poor infants.

Finally, our results indicate that a substantial portion of the effect of socioeconomic status cannot be explained by known environmental exposures. Thus, we should continue to study those at highest risk in order to understand better the factors that subject the socially disadvantaged to excessive burdens of illness. It may be necessary to develop interventions aimed not only at changing exposure to individual risk factors, but also at changing the social, political, and economic environment that promotes the effects of low socioeconomic status. □

Acknowledgments

This research was supported by Grant 28895 from the National Heart, Lung, and Blood Institute, National Institutes of Health; the Robert Wood Johnson Clinical Scholars Program; and the Primary Care Research Training Program. The study was approved by the Committee on Research Involving Human Subjects of the University of North Carolina School of Medicine.

We are grateful to the pediatricians of Alamance and Chatham counties, North Carolina, for supporting our study of their patients. The cooperation of the staffs of Alamance County Hospital, Alamance Memorial Hospital, and North Carolina Memorial Hospital is also greatly appreciated. We thank the staff of the Infant Health Study, whose work made this study possible. We also wish to thank Dr. Robert Fletcher, Codirector of the Robert Wood Johnson Clinical Scholars Program, for encouraging us to pursue this topic and for his guidance while Dr. Margolis conducted this research project as a Robert Wood Johnson Clinical Scholar.

The views expressed are those of the authors and do not necessarily represent those of the Robert Wood Johnson Foundation.

APPENDIX—Estimated Logistic Regression Model Parameters for Estimation of Prevalence of Persistent Respiratory Symptoms

Effect	β	SE	*P*
Intercept	−3.38	.548	.0001
Socioeconomic status	.967	.289	.0008
Crowding	.650	.265	.0141
Tobacco smoke	.347	.328	.291
Feeding	.099	.354	.779
Birthweight	.351	.636	.581
Race	.282	.329	.392
Stress	.155	.178	.383
Day care	.975	.494	.048
Day care × socioeconomic status	−.826	.398	.038

Note. The logistic model had the following form: logit P (persistent symptoms) = −3.38 + .967 (socioeconomic status) + .650 (crowding) + .347 (tobacco smoke) + .099 (feeding) + .351 (birthweight) + .155 (stress) + .282 (race) + .975 (day care) − .826 (day care × socioeconomic status). Exposure to tobacco smoke, bottle feeding and day care, and Black race and low birthweight were coded as dichotomous variables, with the presence of the variable coded as 1. Socioeconomic status (low, middle, high) and crowding (< .5, .5–1, > 1) were coded as three level ordinal variables, with low socioeconomic status and the most crowded living conditions coded as 2. Stress (low, medium, high) was coded into three levels, with the highest level coded as 3.

Call for Papers for Social Policy Journal

Research in Social Policy publishes theoretically informed interdisciplinary analyses of the values, attitudes, beliefs, politics, and organizational contexts of policy makers and their impact on target populations and problems. Critical theoretical and methodological perspectives are encouraged. December 1, 1992, is the deadline for volume 4, "Science and Technology Policy Studies," and June 15, 1993, is the deadline for volume 5, "Medical and Health Policies." Manuscripts should not exceed 40 pages, including notes. Send papers and inquiries to John H. Stanfield II, Department of Sociology, College of William and Mary, Williamsburg, VA 23187-8795.

Imported Leprosy in the United States, 1978 through 1988: An Epidemic without Secondary Transmission

Timothy D. Mastro, MD, Stephen C. Redd, MD, and Robert F. Breiman, MD

ABSTRACT

Objectives. Leprosy remains a major health problem in many regions of the world. In the United States, although leprosy continues to be reported, approximately 90% of cases are imported (i.e., occur among immigrants and refugees). An increase in imported cases began in 1978. This study was conducted to analyze this trend and to characterize the contributing cases.

Methods. Centers for Disease Control leprosy surveillance data from 1971 through 1988 were analyzed.

Results. The number of imported cases reported annually was relatively constant from 1971 through 1977 (mean = 119 per year), increased to 307 in 1985, and then decreased to 102 in 1988. Of the 957 excess cases reported from 1978 through 1988, 73.4% were among persons from Southeast Asia, including 51.3% from Vietnam, Cambodia, and Laos (Indochina). There was no coincident increase in indigenous cases of leprosy; the mean annual number of such cases was 17.7 (range = 10 to 29). Leprosy remains endemic in Texas, Hawaii, Louisiana, and possibly California.

Conclusions. An epidemic of imported leprosy began in the United States in 1978, peaked in 1985, and ended by 1988. This increase was primarily due to cases among refugees from Indochina and was limited by a decrease in the influx of Indochinese refugees in the mid-1980s. There is no evidence that these cases resulted in transmission in the United States. (*Am J Public Health.* 1992:82:1127–1130)

Introduction

Leprosy (Hansen disease) is a major health problem in many regions of the world, affecting more than 11 million persons in the 93 countries where it remains endemic.[1,2] The burden of leprosy is greatest in South and Southeast Asia, Africa, and Latin America.[3] This chronic, debilitating, infectious bacterial disease, caused by *Mycobacterium leprae,* has historically been associated with social stigmatization; before the advent of modern chemotherapy, leprosy patients were traditionally sequestered.[4] In northern Europe, Hawaii, Japan, and the continental United States, the incidence of leprosy had declined well before the introduction of effective chemotherapy in the mid-20th century.[1,5] In the United States, although cases of leprosy continue to be reported, approximately 90% of these cases involve persons entering the country from endemic areas and are defined as imported.[6,7] Leprosy has remained endemic in the United States in Texas, Hawaii, Louisiana, and California.[7] An increase in imported cases starting in 1978 was identified by review of Centers for Disease Control (CDC) surveillance data from 1971 through 1981.[7] We analyzed CDC surveillance data through 1988 to determine whether this trend continued and to characterize the contributing cases. Previously reported cases from 1971 through 1981 were included in the analysis to allow for the evaluation of trends over nearly two decades.[7,8]

Methods

Cases of leprosy are reported to CDC by state and territorial health departments using a standardized report form. Diagnosis is determined by clinical and laboratory (biopsy and/or skin smear) evaluation; type of leprosy is reported as lepromatous, dimorphous/borderline, tuberculoid, or indeterminate. The report includes patient's date of birth, date of entry into the United States, date of onset of symptoms of leprosy, date leprosy was first diagnosed by a physician, and date of report. Cases are categorized as indigenous or imported. Indigenous cases are defined as illness in persons born in the United States who have neither lived nor been stationed for military service outside the country. Imported cases are defined as illness in persons born outside the United States with onset either before or after entering the country, or illness in persons born in the United States who traveled outside the country and may have acquired infection in leprosy-endemic areas. Reports were excluded from the analysis if missing data prevented categorization as imported or indigenous.

Cases were recorded by the year of report, which often differed from the year of onset. Data on immigrant and refugee populations entering the United States were obtained from the US Immigration and Naturalization Service and the Department of State, Bureau for Refugee Programs, respectively. Asian countries were divided into three regions: (1) Southeast Asia—Cambodia, Indonesia, Laos, Malaysia, Myanmar (Burma), Philippines, Singapore, Thailand, and Vietnam; (2) East Asia—China, Hong Kong, Japan, Korea, and Taiwan; and (3) South and

This paper was submitted to the Journal September 30, 1991, and accepted with revisions December 31, 1991.

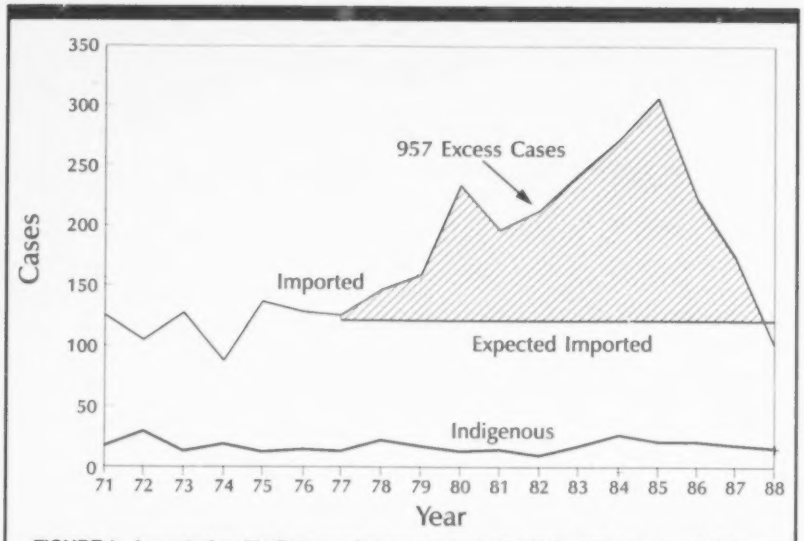

FIGURE 1—Imported and indigenous leprosy cases in the United States reported from 1971 through 1988, and expected and excess imported cases from 1978 through 1988.

West Asia—Afghanistan, Bangladesh, India, Lebanon, Pakistan, Saudi Arabia, Sri Lanka, and Yemen.

The expected annual number of imported cases for each region of the world was calculated using the number of cases reported from 1971 through 1977 as a baseline. Excess cases reported from 1978 through 1988 are defined as the number of cases observed minus the number of expected cases.

Results

Cases

From 1971 through 1988, 3554 cases of leprosy were reported in the United States. Reports of 3420 (96.2%) cases contained sufficient information to be included in the analysis; 3101 (90.7%) were imported, while 319 (9.3%) were indigenous. Of the imported cases, 2973 (95.9%) involved persons born outside the United States. The number of indigenous cases was roughly stable throughout the period, with a mean of 17.7 (range = 10 to 29) reported per year. The number of imported cases reported annually was relatively constant from 1971 through 1977 (mean = 119, range = 88 to 136), increased to 307 cases in 1985, and decreased to 102 cases in 1988 (Figure 1).

Imported Cases

Reports of imported cases were received from 47 states, Puerto Rico, and the District of Columbia. Six states reported 2468 (79.6%) of these cases: California (1306; 42.1%), Hawaii (481; 15.5%), Texas (255; 8.2%), New York (197; 6.4%), Washington (115; 3.7%), and Illinois (114; 3.7%). The mean (± SD) age of persons with leprosy was 38 (±17) years; 63.2% were male. The type of leprosy was multibacillary (lepromatous or borderline) in 67.8% of cases, 28.4% of cases were tuberculoid, and 3.8% were indeterminate.

Persons born in Southeast Asia accounted for 47.8% of all imported cases; however, using 1971 through 1977 as the baseline period to calculate the expected numbers of cases, persons from this region accounted for 73.4% of the excess cases reported from 1978 through 1988 (Table 1). Among cases from Southeast Asia, 743 (50.2%) involved persons from the Philippines and 673 (45.4%) involved persons from the three Indochinese countries of Vietnam (388 cases), Cambodia (215 cases), and Laos (70 cases). However, because of the small number of cases among Indochinese (71 cases) reported from 1971 through 1977, 69.8% of the excess cases from Southeast Asia and 51.3% of all excess cases involved persons from Indochina.

The increase in cases of leprosy imported from Indochina followed an increase in refugees from this area entering the United States (Figure 2). The first large group of refugees arrived in 1975, primarily from Vietnam,[9] followed by large groups in 1979 to 1982 consisting of refugees from Vietnam, Cambodia, and Laos.

Of the excess cases reported from 1978 through 1988, 203 (21.2%) involved persons from the Philippines. The mean annual number of Filipino immigrants to the United States from 1978 through 1988 was 45 025, compared with 34 505 from 1971 through 1977, an increase of 30.5%; the mean annual number of leprosy cases increased 61.7% from 30.0 to 48.5.

Analysis of 1-year cohorts of persons who entered the United States from 1971 through 1988 and who had onset of leprosy after immigration indicates that the highest rates of onset occurred within 12 months of arrival, with a sharp drop in onset during succeeding years of residency. For Filipino immigrants, the rate in the first year was 30.9 per 100 000 immigrants, compared with 16.8 per 100 000 refugees among Indochinese and 4.7 per 100 000 among all other immigrants.

Persons from Indochina with leprosy were younger (mean age = 33 years) than persons from the Philippines (mean age = 43 years; $P < .001$) and other areas (mean age = 38 years; $P < .001$). Onset of leprosy occurred after entry into the United States in only 53.9% of cases from Indochina, compared with 82.4% of cases from the Philippines ($P < .001$) and 78.5% of cases from all other areas ($P < .001$). Also, the mean delay from onset of illness to time of diagnosis was shorter for cases from Indochina (6 months) than for cases from the Philippines (10 months; $P < .001$) and cases from all other countries (11 months; $P < .001$). Leprosy was less commonly multibacillary (lepromatous or borderline) in persons from Indochina (50.8%) and the Philippines (64.5%) than in persons from other countries (77.0%; $P < .001$).

Indigenous Cases

Reports of indigenous cases were received from 17 states; the 4 states where leprosy is endemic reported 298 (93.4%) of these cases: Texas (191; 59.9%), Hawaii (58; 18.2%), Louisiana (40; 12.5%), and California (9; 2.8%). Of the remaining 21 indigenous cases, 10 involved persons who had resided in 1 of these 4 states. The likely place of exposure for the remaining 11 cases could not be determined from reported information. During the 18-year surveillance period, no state had a significant increase or decrease in the number of indigenous cases.

The mean (± SD) age of persons with indigenous cases of leprosy was 49 (±19) years; 53.9% were male. Race/ethnicity was reported as Hispanic for 39.5% of persons with leprosy, 35.7% were non-His-

panic White, 17.6% were Asian or Pacific Islander, and 5.3% were non-Hispanic Black (race/ethnicity was not reported for 2.8%). One hundred ninety-six (61.4%) cases were classified as lepromatous or borderline leprosy, 93 (29.2%) were tuberculoid, and 28 (8.8%) were indeterminate. The mean delay from onset of illness to diagnosis of leprosy was 10 months.

Discussion

An epidemic of imported leprosy in the United States began in 1978 and ended by 1988. The increase was primarily due to cases that occurred among the large groups of refugees that entered the United States in 1975 and 1979 through 1982 from the Indochinese countries of Vietnam, Cambodia, and Laos. The number of cases reported annually among this group decreased after the number of refugees stabilized following 1982.

Imported cases of leprosy appear to present a negligible risk for transmission in the United States; no coincident increase in indigenous leprosy occurred during this time. However, since leprosy has an incubation period of several years and since most household contacts of immigrants and refugees are likely to be immigrants and refugees themselves, it is possible that cases resulting from transmission in the United States would have been categorized as imported cases.

For all groups with imported disease, the highest rate of onset of leprosy occurred in the first year after entry into the United States, and a sharp drop was observed by the second year. Although the prevalence of leprosy in the Philippines was estimated to be 1 to 1.9 cases per 1000 population compared with 5 to 9.9 cases per 1000 population in Indochina,[1] higher rates were observed among immigrants from the Philippines than among refugees from Indochina. The increase in imported cases from the Philippines (21.2% of excess cases) was only partially explained by an increase in immigrants and may have been due, in part, to improved case reporting. However, only 17.6% of cases of leprosy among Filipinos were detected prior to entry to the United States compared with 46.1% of cases among Indochinese, perhaps reflecting a more efficient screening procedure for refugees. Also, methods of counting refugees and immigrants are different, and comparisons of rates of leprosy between these two populations should be made with caution. Refugees are eligible for special processing related to admission to the United States. A refugee's date of admission is recorded by the Immigration and Naturalization Service as the date of entry into the United States as a refugee; few enter uncounted.[10] This is in contrast to immigrants, who are recorded by the year they adjust to permanent resident status, not the year they enter the country. Not reflected in immigrant figures are persons in the United States awaiting adjustment of status and those in the country temporarily and illegally. No rate was calculated for Mexican immigrants because of an inability to accurately estimate the number of Mexicans in the United States at risk for leprosy.

Although refugees and immigrants who entered the United States from 1971 through 1988 were screened for leprosy, the majority of imported cases had onset of illness after entering the United States, with the highest rate of onset in the year following entry. Given the slow progression of clinical signs and symptoms,[4,5] it is likely that many of these persons had clinical evidence of leprosy that was not detected at the time of entry. Although most (67.8%) imported cases were lepromatous or borderline and therefore were potentially infectious, there is no evidence that imported cases of leprosy resulted in transmission in the United States. This apparent lack of transmission may be due, in part, to a combination of better housing conditions, resulting in decreased crowding, and improved nutritional status in the United States. Leprosy transmission is believed to result from prolonged and intimate contact with a person with multibacillary (lepromatous or borderline) dis-

ease; malnutrition is widely considered to predispose to leprosy.[5] In the United Kingdom, despite the diagnosis of more than 1250 cases of imported leprosy since 1951, there have been no reports of secondary cases.[11] A recent investigation of a case of imported active lepromatous leprosy in an elderly man in an English nursing home detected no secondary cases of leprosy, but immunologic studies suggested that *M. leprae* may have been transmitted (leading to subclinical infection) to 2 of 66 persons with whom the index case had daily contact.[11]

The data presented here provide additional evidence that persons with imported leprosy, including lepromatous forms, do not pose an appreciable infectious risk in the United States. Furthermore, current chemotherapy, which should be initiated promptly following diagnosis, is highly effective for all forms of leprosy; infectiousness is generally lost within 3 days of treatment with a multidrug regimen including rifampin.[3,12] Leprosy, active tuberculosis, human immunodeficiency virus infection, and five bacterial sexually transmitted diseases were classified in the Immigration and Nationality Act as "dangerous contagious diseases" for which aliens may be excluded from admission to the United States.[13,14] This study supports the proposed change to this act that would remove leprosy from the newly named list of "communicable disease of public health significance."[13,14] Continued classification of leprosy as an excludable condition unjustifiably furthers the social stigmatization historically associated with this diagnosis.

The World Health Organization has recently set as a goal the worldwide elimination of leprosy as a public health threat; elimination was defined as the reduction of prevalence to below one case per 10 000 population.[2] In the United States, continued surveillance for leprosy will be necessary to monitor changes in the distribution of indigenous cases, in particular, to further document the decrease in cases in Hawaii[15] and to determine whether the small number of reported cases in California truly represents endemic disease. Surveillance is also important to monitor trends in imported disease and to determine whether household contacts, notably children, of immigrants and refugees are at increased risk for leprosy.

Clinicians should be familiar with the clinical manifestations of leprosy and consider the diagnosis, particularly for persons from leprosy-endemic areas, both in the United States and abroad. All household contacts of persons with leprosy should be thoroughly evaluated for disease.[16] Even if indigenous leprosy is eliminated in the United States, immigrants and refugees entering the country from leprosy-endemic areas are likely to continue to present with new cases of disease. □

Socioeconomic Status and Childhood Mortality in North Carolina

ABSTRACT

Children in families eligible to receive Aid to Families with Dependent Children (AFDC) were found to have substantially higher mortality rates than non-AFDC children. The disparity seems to be greater for Whites than for non-Whites. These results suggest the presence of social class differentials in access to and use of health care and related services and facilities, in exposure to environmental risks, and in knowledge of injury control measures. (*Am J Public Health.* 1992;82:1131–1133)

Melvin D. Nelson, Jr, MBA

Introduction

The relationship between socioeconomic status and health was first documented in this country in 1925[1] and has since been widely recognized.[2–13] The present study assesses the differences in mortality between children in families eligible to receive Aid to Families with Dependent Children (AFDC) and those not eligible for such aid from July 1, 1985, through December 31, 1988.

Methods

Lacking a more suitable indicator of poverty, the population of AFDC recipients and Medicaid participants who are eligible for AFDC was used as a surrogate. Children in the AFDC and AFDC-eligible Medicaid registries were matched to child death certificates. Death certificates for 3679 children aged 28 days through 17 years who died from July 1, 1985, to December 31, 1988, were matched with AFDC and AFDC-eligible Medicaid files for the same period. Decedents under 28 days of age were excluded because the short time between birth and death may have precluded the certification of AFDC eligibility of some otherwise potentially eligible children. Five hundred sixteen of the 3679 decedents were, at some time during this period, recipients of AFDC.

By race and age group for July 1, 1985, through December 31, 1988, unduplicated counts of AFDC eligibles aged 17 or younger were obtained. These figures were subtracted from the North Carolina population by race and age group for the same period to obtain figures for the non-AFDC population. Whether the ratio of an AFDC to a non-AFDC mortality rate was statistically different from 1.0 was determined by dividing the difference between the natural logs of the rates by the standard deviation of that difference to yield a z score.

Results

As shown in Table 1, the ratio of AFDC to non-AFDC death rates reveals that AFDC children aged 28 days through 17 years experienced a mortality rate 2.7 times that of their non-AFDC counterparts. The disparity seems to be even greater for Whites than for non-Whites.

In many cases, the cause-specific ratios are alarming. For all childhood age groups combined, AFDC children were 6.9 times more likely than non-AFDC children to die from fire and 6.1 times more likely to die from poisoning. Mortality from homicide and mortality from pneumonia or influenza were 4.7 and 4.8 times as high, respectively, for AFDC eligibles than for noneligibles. Heart disease claimed the lives of AFDC children 3.8 times more often than it claimed the lives of non-AFDC children. AFDC eligibles were 5.4 times more likely to die from perinatal conditions, 3.5 times more likely to die from congenital anomalies, 3.1 times more likely to suffer death from unintentional injuries, 2.3 times more likely to die from drowning, 1.8 times more likely to die from cancer, and 1.4 times more likely to suffer a motor-vehicle fatality.

Note. AFDC = Aid to Families with Dependent Children; Unin non-MV injuries = unintentional non-motor-vehicle injuries; Accid mech suffoc = accidental mechanical suffocation; IICO = inhalation or ingestion causing obstruction. Nonsignificant and incalculable ratios are not reported.
*$P < .05$.
**$P < .01$.
***$P < .001$.

The age-specific ratio of AFDC to non-AFDC eligibles is greatest at ages 1 through 4 (2.9) and least at 28 days to 1 year (1.6). For the 15- through 17-year-olds, the ratio of total mortality rates of AFDC to non-AFDC eligibles is not significantly different from 1.0.

For specific age groups and causes of death, some ratios of AFDC-eligible to non–AFDC-eligible death rates are remarkably high. AFDC eligibles 1 to 4 years of age are 9 times more likely to suffer death from fire than their non-AFDC counterparts. AFDC eligibles 10 to 14 years of age are 24.2 times more likely to die from pneumonia or influenza and 15.4 times more likely to be a victim of homicide than their non-AFDC counterparts. AFDC-eligible decedents 15 through 17 years of age are 22.9 times more likely to die from poisoning than their counterparts. Other age/cause-specific ratios, along with age/cause/race-specific ratios, can be found in Table 1.

Controlling for poverty, that is, comparing the mortality rates of AFDC non-Whites and AFDC Whites, the marked disparity between the races is not present as is the case in the general population. The AFDC non-White to AFDC White mortality ratios are not significantly different from 1.0 for specific age/cause groups or for all ages and causes combined.

Discussion

The overall childhood mortality rate of AFDC eligibles is nearly three times the rate of children not eligible for such aid. On an age/cause-specific basis, the disparity is even more extreme. Furthermore, no statistical difference is found between the mortality rates of non-White AFDC children and their White counterparts.

The strong association between childhood mortality and socioeconomic status points to the existence of social class differences in housing, nutrition, education, exposure to environmental risks, and access to and use of health care and related services and facilities.

That poor children die from endogenous causes such as cancer, heart disease, and pneumonia/influenza, as well as from congenital anomalies and perinatal conditions, at two to five times the rates of non-poor children suggests that parents or guardians of poor children either postpone seeking medical care until it is too late to benefit or do not have access to medical care.

The relationship of socioeconomic status to exogenous causes of death is not as well documented. That fire takes the lives of AFDC children at nearly seven times the rate of children not enrolled in AFDC suggests that substandard housing among the poor and their inability to afford smoke detectors may be a factor. Other researchers have reported a greater risk of house fires in rental property[14] and a lower rate of smoke detector installation by renters than by homeowners.[15]

AFDC-eligible children also die at a higher rate from the other exogenous causes

shown in Table 1, suggesting a greater exposure to a hazardous and violent environment. These exogenous causes also need traditional public health interventions such as legislation, education, or education.

The large differences in mortality rates between poor and nonpoor youth for these and other causes warrant further studies to determine, on a cause-specific basis, the reasons for these mortality differentials. □

Does Equal Socioeconomic Status in Black and White Men Mean Equal Risk of Mortality?

Julian E. Keil, MS, DrPH, Susan E. Sutherland, MS, Rebecca G. Knapp, PhD, and Herman A. Tyroler, MD

ABSTRACT

Although concerns have been expressed that mortality from coronary disease and all other causes is greater among Blacks than Whites, we hypothesized that, when socioeconomic status is adequately considered, mortality inequalities between Blacks and Whites are insignificant. The study population was a random sampling of Black and White men who were 35 years of age or older when recruited into the Charleston Heart Study in 1960. Education level and occupational status at baseline were used to compare mortality over the ensuing 28 years between Black and White men, who were classified as low or high socioeconomic status. In no instance were Black-White differences in all-cause or coronary disease mortality rates significantly different when socioeconomic status was controlled. We conclude that socioeconomic status is an important predictor of mortality and that, when socioeconomic status is considered, differences in Black-White mortality rates may be small. (*Am J Public Health.* 1992;82:1133–1136)

Introduction

In the early 1970s Terris[1] expressed disdain for evaluation of health statistics by race, contending that the appropriate variable for comparison was socioeconomic status. Despite evidence by Antonosky, Kitagawa, Kaplan, Feldman, Marmot, and Haan[2–7] of an inverse relationship between socioeconomic status and mortality, studies have continued to focus on ethnicity. Such studies[8–9] identify a racial difference in risk factors for mortality but, in most instances, use the concept of socioeconomic status to explain the reported difference. Nevertheless, these studies have served social and humanitarian purposes by identifying underserved populations at particular risk of disease or death. In the Charleston Heart Study cohort, low socioeconomic status was found to be a significant predictor of the incidence of hypertension, while skin color was not.[10] Recently, Gillum[11] has shown that mortality from coronary heart disease or from all other causes among Blacks has been greater than among Whites. The purpose of this report is to provide additional evidence from the Charleston Heart Study to support the hypothesis that socioeconomic status is a key predictor of mortality when ethnicity is controlled.

Materials and Methods

The study population in Charleston, SC, was a random sampling of Black and White men who were 35 to 74 years of age

[a]Codes 410–414 of the *International Classification of Diseases*, 9th version, from nosologist coding of underlying cause of death.

in 1960. Details of the baseline examination and sampling plan have been previously published.[12] In 1963, the cohort was supplemented with 102 Black men of high socioeconomic status who had been recruited by peer nomination to provide an extended range of economic status in Blacks. Between 1960 and 1988, there were four recalls of the cohort. Table 1 provides the vital status of the cohort through 1988.

While there was a wide range of education and occupations among White men, more than 85% of randomly selected Black men had 8 years or less of education and 75% were in the lower occupation groups of laborer, protective service worker, craftsman, or operative (Figure 1). To assess the influence of both race and socioeconomic status, comparisons of age-adjusted coronary heart disease and all-cause mortality rates[13] were made in four groups: Black, White, low socioeconomic status, and high socioeconomic status. Low socioeconomic status was defined as having 0 to 8 years of education and being in the lower occupation group. High socioeconomic status was defined as having some college education and an occupation of proprietor or professional.

The participants of low socioeconomic status included in the analyses were from the random sampling of 1960. For high socioeconomic status, the White men were from the random sampling of 1960, while most of the Black men were from the special cohort recruited in 1963. Baseline characteristics are described in Table 2.

Results

Table 3 provides a comparison of mortality among Black and White male participants in the Charleston Heart Study when socioeconomic status criteria are strictly met, and also provides estimates of the effect of socioeconomic status while controlling for race. White men had higher rates than Black men, regardless of socioeconomic status or cause of death. In no instance was the White–Black difference in rates statistically significant, although the White–Black ratio for coronary heart disease mortality among men of low socioeconomic status was 1.8 (7.1/4.0). Among Whites for all causes of death, men of low socioeconomic status had rates 1.8 times those of men of high socioeconomic status. The rate ratio was 2.1 for coronary heart disease mortality. Among Blacks, the low–high socioeconomic status ratio was 2.1 for all-cause mortality and 1.6 for coronary heart disease mortality.

Discussion

There is evidence in both White and Black men that socioeconomic status has a powerful influence on coronary mortality and death from all causes. In every comparison controlling for socioeconomic status, the rates for Black men were slightly, but not significantly, lower than for White men.

TABLE 2—Charleston Heart Study Baseline Characteristics of Men Aged 35–74 by Socioeconomic Status

[a]Education = less than 8 years; occupation = craftsman, operative, protective, farm laborer, or other laborer.
[b]Education = some college or greater; occupation = professional or proprietor.

Black men of low socioeconomic status had lower baseline levels of education, higher blood pressure, more electrocardiogram left ventricular hypertrophy, and less access to medical care, but had lower cholesterol and were younger, than the White men. Age adjusting the risk factors of the low socioeconomic status group had the effect of increasing the risk factors of Black men, yet their mortality rates were lower. White and Black men of high socioeconomic status had comparable characteristics. Blood pressure was higher and cholesterol was lower in the low than in the high socioeconomic status ethnic peer group. In both socioeconomic status groups, Black men had lower mortality rates than White men. Black men of lower socioeconomic status had 13.7% lower all-cause rates and 43.1% lower rates for coronary heart disease mortality than Whites. Black men of high socioeconomic status had 24% lower all-cause and 32% lower coronary heart disease mortality than White men of high socioeconomic status.

TABLE 3—Mortality Rates,[a] 1960–1988: White and Black Men

	All-Cause Mortality			Coronary Heart Disease Mortality		
	n	Age-Adjusted Rate	(95% CI)	n	Age-Adjusted Rate	(95% CI)
Low socioeconomic status						
White men (n = 151)	101	20.9	(13.5, 28.3)	33	7.1	(2.2, 11.9)
Black men (n = 258)	159	18.0	(14.3, 21.7)	36	4.0	(2.2, 5.9)
High socioeconomic status						
White men (n = 115)	59	11.5	(7.5, 15.4)	22	3.5	(2.0, 5.0)
Black men (n = 77)	30	8.7	(5.6, 11.8)	8	2.4	(0.7, 4.1)

[a]Age-adjusted rate per 1000 person years.

Our findings may be mediated by the Black–White mortality crossover effect reported by Wing[14] that suggests that once Blacks attain age 65 they have preferred survival status. It has also been postulated that socioeconomic status may have opposite effects during the earlier and later periods of the coronary heart disease epidemic. This concept, suggestive of a socioeconomic status crossover, was demonstrated by Marmot[15,16] to show "that as the CHD [coronary heart disease] epidemic grew in industrialized countries, it affected first the more affluent classes and then percolated through the social classes." A similar finding in the Evans County, Georgia, cohort was reported by Morgenstern.[17] For the Charleston Heart Study cohort, a socioeconomic status crossover effect was not detected. However, since Black men of low socioeconomic status had lower rates and fewer years of education and were more likely to be laborers than White men, a protective effect for these men is suggested. Our findings of lower mortality in Black men of low socioeconomic status may suggest that they were acculturating at a rate somewhat slower than White men of low socioeconomic status, providing evidence for Marmot's thesis.

Finally, more positive interpretations of our results are difficult because of the relatively small sample size and the commensurate large confidence intervals around the estimates of mortality.

While our results are comforting in that Black men per se may not have higher mortality than White men, they may also provide further evidence of the validity of

Antonosky's exclamation[2] of the 1960s: "The inescapable conclusion is that class influences one's chance of staying alive." □

Job Strain and Mortality in Elderly Men: Social Network, Support, and Influence as Buffers

Anders Falk, MD, Bertil S. Hanson, MD, Sven-Olof Isacsson, MD, and Per-Olof Östergren, MD

ABSTRACT

The aim was to investigate whether job strain affects mortality in a representative population of elderly men, and whether social network and social support outside the workplace can buffer the negative health effects of job strain. A higher relative mortality risk (RR) was found among men exposed to job strain (RR = 1.7). The combination of exposure to job strain and seven different measures of weak social network and social support was associated with a further increased RR ranging from 2.1 to 4.6. (*Am J Public Health.* 1992;82:1136–1139)

Introduction

In 1979, Karasek proposed a two-dimensional model for measuring psychosocial work conditions, in which the combination of high psychological job demands and low personal schedule freedom (job strain) was found to be associated with depression, exhaustion, and job dissatisfaction.[1] After that, several studies found associations between job strain and cardiovascular disease.[2–6] Job support was later added as a third concept in a three-dimensional model (iso-strain).[7–8]

Social network and social support have been shown to affect morbidity and mortality,[9–13] and it has been suggested that they may have a buffering function on the negative health effects of different stressors.[14]

Previous studies on the health effects of job strain have all been performed on active, working populations. No studies have investigated the chronicity of job strain and its effects on health in elderly people.

The aims of this study are therefore to investigate whether exposure to job strain during the active working period affects mortality in elderly men after retirement and to investigate if the social network and social support outside the place of work can buffer the negative health effects of job strain.

This paper was submitted to the Journal April 9, 1991, and accepted with revisions December 31, 1991.

Methods

All 621 men born in even months in 1914 and residing in the city of Malmö, Sweden (about 230 000 inhabitants), during 1982 to 1983 formed the study sample. Five hundred men (80.5%) agreed to participate, 23 only partially.[15]

The investigation took place during 1982 to 1983, 3 years after the participants' retirement. Interviews, questionnaires, and physical and physiological examinations were used to obtain information about health status, life-style, the psychosocial working environment, social network, and social support.

The dichotomous job strain variable was constructed by combining high job demands and low personal schedule freedom according to a method described by Karasek et al.[3] Affirmative answers to two questions (Was your job hectic? Was your job psychologically demanding?) were used to define high job demands. Low personal schedule freedom was defined as negative answers to at least two of three questions (Could you make at least one private phone call of about 10 minutes during working hours? Could you go on a private errand for about 30 minutes without asking a superior? Could you receive a private visitor for about 10 minutes during working hours?).

The indices measuring different aspects of social network and social support have been described in detail previously (see appendix).[16-17] Social network includes social anchorage (sense of anchorage within formal and informal groups), contact frequency (contacts with family, neighbors, friends), and social participation (degree of participaion in social activities).

Social support includes emotional support (opportunities to receive care and personal encouragement), informational support (access to guidance and information), and material support (access to practical services and material resources).

Low social network and social support was defined as the lowest third of the distributions of the indices.[17]

Mortality of the cohort was followed continuously until February 28, 1989, using the Cause of Death Register both at the Department of Community Health Sciences in Malmö and at the Swedish National Central Bureau of Statistics.

TABLE 1—Relative Mortality Risks between High and Low Categories of Social Network and Social Support

	Relative Mortality Risks	95% CI
Social network		
Contact frequency	1.2	0.8, 1.8
Social anchorage	1.6	1.1, 2.3
Social participation	1.2	0.8, 1.8
Adequacy of social participation	1.9	1.1, 3.4
Social support		
Availability of material and informational support (low/high)	1.4	0.9, 2.0
Availability of emotional support	1.8	1.2, 2.8
Adequacy of emotional support	1.3	0.8, 2.0

Note. Figures are for men born in 1914 and residing in Malmö, Sweden, during 1982 to 1983.

The relative mortality risks (RR) were calculated using risk odds ratios and multivariately using logistic regression analysis. Homogeneity of the RRs was tested with a chi-square test for homogeneity.

Results

Eighty-seven men (18.2%) of the 477 full participants died during the follow-up. Men exposed to high demands had an RR of 1.3 (0.8–2.0), and those exposed to low personal schedule freedom had an RR of 0.7 (0.5–1.2). Men exposed to job strain showed a higher all-cause mortality rate (23/91) than those not exposed (64/386) (RR = 1.7 [1.0–2.3]). Adjustment for social class, cardiovascular risk factors, and

[a]CI = 95% confidence intervals.
[b]Chi-square test for homogeneity.

variations in follow-up time did not change the relative risk very much (RR = 1.6 [1.0–2.5]).

The RRs for men with a low score on the social network and social support indices were compared with those for men with a high score (Table 1). All indices showed RRs higher than 1.0.

A multicategorial analysis was performed to investigate if there was evidence of a buffering effect (i.e., effect modification) between job strain and social network and social support (Table 2). The RRs regarding exposure to job strain were highest in the groups exposed to low social network and social support, ranging from 2.1 to 4.6, using the group with no job strain/high social network and support as reference (RR = 1).

Discussion

Considering the high participation rate together with the fact that the health differences between the participants and the nonparticipants were rather small, the participants could be regarded as fairly representative of this population of elderly men.[15]

The individual's view of his personal schedule freedom probably was not affected too much by the fact that 3 years or more had passed between being in active work and participating in this study. The assessment of job demand, however, was more indirect and measured the sum of several components of the psychosocial work conditions. A nondifferential misclassification because of a fading recollection of the actual job situation, however, meant an underestimation of the true mortality risks.

The association between job strain and mortality could be the result of social class differences or of a higher prevalence of risk factors in the strain group. However, such effects did not show in the multivariate analysis, consistent with other studies.[4]

The health effect of social network and social support may be mediated through different causal pathways. One such pathway is described by the buffering hypothesis; i.e., social network and social support are mobilized in response to environmental stressors.[14] Men with a combination of high job strain and insufficient social network and social support showed the highest mortality risks, thus supporting a buffering effect.

Our findings indicate that exposure to job strain also influences the risk of mortality after retirement, and that social network and social support outside work seem to buffer the negative health effects of job strain. □

APPENDIX

The following items were included in the interview questionnaire that measured the different aspects of social network and social support.

Social Anchorage

Would you say that you are rooted and have a feeling of familiarity with your neighborhood?

How many years have you lived in your neighborhood?

If you were able to move now, would you do so?

Do you belong to a group of friends that does things together, i.e., play cards, listen to music, go on picnics, etc.?

In your daily life, do you have use for the knowledge and skills you have acquired during your life?

Do you feel that you are of great importance to other people and that you have a useful function in society?

Are you a member of any organizations or clubs?

Are you in any position of trust in any organizations or clubs?

Contact Frequency

How often do you meet any of these persons (children, kin, neighbors, friends, close friends, workmates) at your or at their homes?

Social Participation

How often in the last year have you taken part in study circles and other courses?

How often do you take part in meetings of different organizations, clubs, etc.?

Have you done any of the following during the last 12 months: written an article, taken an active part in the discussion at a meeting, taken part in a political meeting, tried to influence a decision regarding a political question, appealed against a decision, contacted a consumers' association, gone to a salesman or shop in order to complain, taken part in a political or union rally?

How often in the last year have you been to parties at your friends', relatives', or neighbors' homes?

How often in the last year have you been to church?

Did you vote in the referendum concerning nuclear power?

Adequacy of Social Participation

Are you satisfied with your opportunities for participating in different activities?

How important do you think that your activities are to you?

How often do you find it a problem to occupy yourself?

Availability of Material and Informational Support

Is there anyone in your neighborhood from whom you can borrow things or exchange services?

Is there anyone in your neighborhood from whom you can get help if you fall ill?

If you need help with something for 24 hours, do you have anyone (other than wife) you can ask?

Do you know anyone who can help you to write an official letter or appeal against a decision made by some authority?

Do you know where to go to get help in writing an official letter or appealing against a decision made by some authority?

Availability of Emotional Support

Do you have any friends or relatives who you like very much and who like you very much?

Do you have any really close friends with whom you feel intimate and with whom you can discuss anything?

If you have continued to work, is it because you want to feel that you are a valuable and important person?

When you have personal problems of any kind, do you have any close friend or relative to whom you can turn to discuss your problems?

Adequacy of Emotional Support

How often do you feel lonely?

Do you have the feeling that people appreciate what you do?

Do you have enough good friends to be with?

Do you think that you see your children too often or too rarely?

Mortality and the Attribution of Health Problems to Aging among Older Adults

William Rakowski, PhD, and Tom Hickey, DrPH

ABSTRACT

This study examined the association between mortality and attributing health problems to aging among 1391 respondents from the Longitudinal Study of Aging who indicated difficulty with activities of daily living. Of this number, 72 persons attributed impairment primarily to "old age." Logistic regression controlling for demographics, physical health problems, self-rated health, and social involvements showed an association with mortality (adjusted odds ratio = 1.78, CI = 1.05, 3.00). Attributing health problems to aging may carry a risk of adverse health events. (*Am J Public Health.* 1992;82:1139–1141)

Introduction

Research in gerontology continues to try to distinguish effects of disease from effects of aging on physical health and functioning.[1–3] Public information and professional education increasingly emphasize that attributing health problems to supposedly inevitable consequences of old age is inappropriate. The current emphasis on disease prevention and health promotion with older persons[4–6] reflects a growing recognition that chronological aging per se imposes significantly fewer limitations than was previously assumed.

It is important to understand the potential consequences of laypersons, professionals, and the general public attributing health problems to aging. Leventhal and Prohaska[7] report that attribution to aging is associated with a tendency to delay seeking care. Gjorup et al.[8] found that attribution to aging exceeds 60% for some conditions and is associated with delay in contacting a physician, while Brody and Kleban[9] note that such attribution is associated with reluctance to discuss health problems with other people or health care providers. It was therefore expected in this study that persons who made attributions to aging would have higher mortality.

Methods

Sample

The sample for this investigation was self-respondents at baseline in the 1984–1988 Longitudinal Study of Aging (LSOA) who reported difficulty with one or more activities of daily living (ADLs) (n = 1391). The baseline for the LSOA was the Supplement on Aging to the 1984 National Health Interview Survey. All LSOA participants

Independent Variable	Number	Percent Died	Odds Ratio	95% CI
ADL attributions to aging				
None	1319	30.0	(reference category)	
One or more	72	45.8	1.97	1.22, 3.18

TABLE 2—Multivariate Association between Mortality and ADL Attribution to Aging: Results from Logistic Analysis

Independent Variable	Adjusted Odds Ratio (AOR)	95% CI
ADL attributions to aging		
None	(reference category)	
One or more	1.78	1.05, 3.00

$-2 \times$ log-likelihood ratio change = 4.58, $df = 1$, $P < .05$

Note. Other predictors with 95% CIs excluding 1.00 are cancer (AOR = 1.54, 1.05–2.15), diabetes (AOR = 1.74; 1.23–2.44), male sex (AOR = 1.77; 1.33–2.36), age 80 to 84 (AOR = 1.86; 1.32–2.63), age 85+ (AOR = 2.32; 1.56–3.44), no. instrumental ADLS (AOR = 1.20; 1.10–1.30), self-rated health (AOR = 1.21; 1.07–1.36), body mass index (AOR = 1.18; 1.08–1.29), and social involvement (AOR = 1.31; 1.09–1.59).

were aged 70 and older in 1984. The 1984 interviews were conducted by Census Bureau staff at the individual's residence; the 1988 follow-up was conducted primarily by computer-assisted telephone interview.[10–12]

Independent Variable: Attribution of Problems to Aging

The ADLs assessed by the LSOA comprise dressing, bathing, using the toilet, eating, walking, getting outside, and transferring, and indicate basic functional health status.[13,14] A report of ADL difficulty was followed by questions about degree of difficulty, receipt of help, use of aids, and perceived cause(s) of an impairment. The attribution question allowed giving multiple causes for the impairment; if multiple causes were mentioned, respondents were asked to select one as the main cause. Therefore, persons classified for this report as attributing a problem to aging were those who chose aging as the main cause. The independent variable was defined as no ADLs attributed to aging versus one or more ADLs attributed to aging. (Note: Attribution to aging was not requested for physical health problems such as stroke, heart disease, cancer, etc.)

Dependent Variable: Vital Status

Mortality was based on the National Center for Health Statistics' "best estimate" of vital status, derived from tracking information through December 1988. In the analysis sample of 1391 persons, there were 429 deaths (30.8%).

Covariates for Logistic Analysis

Several other variables from the LSOA were used as covariates in logistic regression analysis. They included any heart problem, any circulatory problem, diabetes, stroke, cancer, gender-specific body mass index, number of limitations to instrumental ADLs, age, gender, education, race, living alone or with others, self-rated health, and an indicator for social contacts (based on group or social events out-of-home, volunteer work, and attendance at religious services).

Results

Bivariate Associations

Table 1 presents the bivariate associations between mortality and the attribution of ADL problems to old age over the 1984 to 1988 period. The number of persons who cited only old age as a cause was small (n = 72). However, an elevated risk of mortality did appear to exist.

Multivariate Associations

Results of logistic regression are shown in Table 2. Analyses were done with BMDP and unweighted data. Even controlling for the covariates listed above, the attribution of ADL difficulty to aging was associated with a higher risk of mortality, as denoted by the adjusted odds ratio (OR) and change in the log-likelihood ratio due to attribution. Other covariates associated with higher mortality were having had cancer or diabetes, being age 80 or over, being male, having difficulty with more instrumental ADLs, being in the lowest quintile for body mass index, having less favorable self-rated health, and having fewer social involvements.

Correlates of Attribution to Aging

In other analyses, few variables from the covariates listed above and from other questions from section T ("Health Opinions") of the baseline survey were found to be correlates of attributing ADL difficulty to aging. Table 3 presents bivariate associations for those variables. Several associations suggested greater aging attribution when health ratings were favorable. Multiple logistic analyses using none versus one or more attributions as the dependent variable indicated a greater likelihood of attribution for persons aged 80 to 84 (adjusted odds ratio [AOR] = 2.65; 95% CI = 1.16, 6.06) and aged 85 or over (AOR = 6.57; 95% CI = 2.95, 14.70), relative to persons aged 70 to 74 at baseline.

Discussion

Results of this investigation suggest a potential adverse consequence of attributing at least some types of health problems to old age as opposed to a specific disease. As hypothesized by Kart,[15(p78)] "Overattribution of symptoms to the aging process directs the attention of the elderly person away from real disease and/or environmental factors that may affect health. Such misattributions may have tragic consequences." Although the number of persons making such attributions was small, the database was a national sample and results are consistent with the above hypothesis and with data from earlier studies.[7–9]

In actuality, the number of persons making attributions to aging was probably underestimated because respondents were asked to choose a main cause if several were given. The group identified here is therefore selective and may represent individuals for whom attribution to old age has special significance. Their attribution may denote a cumulative judgment of "how bad things really are." Attributions to aging may be one factor differentiating "normal" from "successful" aging, as discussed by Rowe and Kahn,[1] and may also be another manifestation of self-rated health.[16] Global self-rated health, along

with social involvement, predicted mortality even in this impaired sample (Table 2).

The processes by which attribution to aging operate need further study. Table 3 suggests that aging attributions may occur when individuals report good health despite functional limitations. If individuals retain positive subjective assessments despite reporting physical impairments, old age may be a convenient and socially accepted explanation for the decline even though it is not specific. Other possibilities include less effective self-care, adherence to treatment, health-promoting actions,[17] or perhaps denial of the severity of problems. Whatever the processes, however, family caregivers and health care professionals should attend to comments indicating a belief that old age is the cause of health problems. Otherwise, the expected negative trajectory of aging may become a self-fulfilling prophecy with unfortunate consequences. □

TABLE 3—Bivariate Associations between Other Variables[a] and Attribution of ADL Impairment to Aging

Associated Variable	% Attributing to Aging	Odds Ratio	95% CI

Use of Cardiovascular Disease Medications and Mortality in People with Older Onset Diabetes

Barbara E. K. Klein, MD, MPH, Scot E. Moss, MA, and Ronald Klein, MD, MPH

ABSTRACT

Mortality follow-up for a cohort defined in 1980 with diabetes diagnosed at 30 years of age or older has been completed through 1988. History of medication use was obtained during the initial evaluation. There were 605 (44.2%) confirmed deaths; heart disease was the underlying cause in 49.9% of the deaths. Use of loop diuretics was associated with an odds ratio of death of 1.8 (95% CI = 1.4, 2.2). Although a causal relationship cannot be inferred, it is reasonable to suggest that blood chemistries be monitored regularly in persons on these drugs since electrolyte imbalance may be related to death. (*Am J Public Health.* 1992;82: 1142–1144)

Introduction

Diabetes mellitus increases the risk of death in several populations in the United States.[1–6] Much of the increase is attributed to cardiovascular disease. People with diabetes are more likely to have cardiovascular disease, including high blood pressure.[7,8] Thus, in addition to therapy for their diabetes, these people may also be taking medication to lower blood pressure and for other cardiovascular problems. Warram has reported excess mortality associated with diuretic usage in patients followed at the Joslin Clinic.[9] We explore the relationship between use of cardiovascular medications and mortality in people with diabetes diagnosed after 30 years of age in the population participating in the Wisconsin Epidemiologic Study of Diabetic Retinopathy.

Methods

The population has been described in previous reports.[10–12] Briefly, 10 135 diabetic persons were identified from the records of physicians providing primary care in an 11-county area in southern Wisconsin from July 1, 1979, through June 30, 1980. A probability sample of persons diagnosed as having diabetes after age 30 (n = 1780) was invited to the examination phase of the study from 1980 to 1982 (1370 participated). Pertinent parts of the examination included measurements of weight, height, blood pressure,[13] glycosylated hemoglobin,[14] and gross urine protein (Labstix). An interview included questions about medications for control of hyperglycemia and blood pressure and diuretic agents. We asked for the number of aspirin used in the 30 days before the baseline examination, and about smoking, angina, myocardial infarction, and stroke. Questions about medication usage were verified by a physician's report.

Participants, relatives, and contact persons have been called annually to determine vital status. Newspaper obituaries were reviewed daily. Annually, a request was made to the Wisconsin Center for Health Statistics, Section of Vital Statistics, for death certificate information for these persons. Names of persons who had been lost to follow-up were submitted for matching against death records. Wisconsin death records through 1988 have been searched. Information on persons who have moved out of Wisconsin and were suspected of being deceased and on those lost to follow-up was submitted to the National Death Index for matching against national death data.

The time interval of interest for this study ranges from the examination date through the date of death or December 31, 1988. Only deaths confirmed by a death certificate are included in the analyses. Cause-specific mortality analyses are based on the underlying cause of death or any mention on the death certificate.

People were classified as having a cardiovascular disease at examination if they reported that they had angina or had had a heart attack or stroke that was verified by a physician. People were classified as having never smoked if they had smoked fewer than 100 cigarettes in their lifetime. Proteinuria was classified as a urine protein concentration of 0.30 g/l or more as measured by Labstix.

The Cox proportional hazards model was used to evaluate the effect on mortality of a medication while controlling for other risk factors.[15] The Statistical Analysis System was used for estimating the model parameters.[16]

Results

There were 605 (44.2%) confirmed deaths (Table 1). Heart disease (codes

[a]Medications considered: aspirin, beta blockers, centrally and peripherally acting anti-adrenergic agents, vasodilators, K-sparing diuretics, loop diuretics, thiazide diuretics, acetohexamide, chlorpropamide, tolbutamide, and tolazamide.
[b]Controlling for age, sex, systolic blood pressure, presence of proteinuria, history of cardiovascular disease, history of cancer (for cancer as a cause of death only), smoking history, body mass, duration of diabetes, glycosylated hemoglobin, and insulin use.

391–398, 402, and 404–429 of the *International Classification of Diseases*, 9th version) was listed as the underlying cause of 49.9% of deaths. Table 2 lists the frequencies of antihypertensive and diuretic medications, aspirin, and tolbutamide use. Many subjects took more than one of these medications.

The odds of death for use of these medications were computed. Other relevant characteristics included in the analyses were age, duration of diabetes, use of insulin (no or yes), systolic and diastolic blood pressures, glycosylated hemoglobin (as a percentage of hemoglobin), sex, body mass index (weight/height^2), smoking status (current, past, or never smoked), and presence of proteinuria. The latter was included in an attempt to control for the presence of renal disease. The odds of death as derived from proportional hazards analyses appear in Table 3. The use of loop diuretics was associated with all causes of mortality and with mortality attributed to diabetes, heart disease, and ischemic heart disease. Use of thiazide diuretics was associated with death due to heart disease, other than ischemic, and with stroke. Potassium sparing diuretics were associated with all other causes of mortality. These analyses were repeated after excluding those who had proteinuria. There was no change in the pattern of significant associations between use of loop diuretics and death. Also, major drug combinations were examined. These included use of a beta blocker or potassium sparing diuretic with a thiazide diuretic and use of a beta blocker or potassium sparing diuretic with a loop diuretic. In all cases, except for the association of loop diuretics with death due to other heart disease, the effect of loop and thiazide diuretics remained significant after controlling for use of beta blockers or potassium sparing diuretics and interactions with these agents.

TABLE 2—Frequencies of Reported Use of Selected Drugs in the Cohort

Drug	n	%
Alpha blockers	23	1.7
Beta blockers	120	8.8
Loop diuretics	177	12.9
Thiazide diuretics	552	40.3
Potassium sparing diuretics	176	12.8
Vasodilators	58	4.2
Aspirin	338	25.0
Tolbutamide	117	8.5

Discussion

Patients with diabetes mellitus are at increased risk of death due to cardiovascular diseases.[17] One might anticipate that the presence of these diseases would necessitate the use of any of the medications of interest in this paper. Therefore, in order to attempt to control for this "confounding by indication," we included a history of cardiovascular disease in our analyses. For each cause of death cate-

gory, history of cardiovascular disease was a significant variable. However, use of at least one diuretic agent added significant information for most of the models. Loop agents were the agents most frequently included, but thiazide diuretics were also significantly associated with an increased risk of death. The differences between the analyses indicating one class of diuretics as important compared with another may be a reflection of the frequency of their use rather than the particular drug effect. In clinical practice, nephrologists may avoid using thiazides because of their effects on glycemia and uricemia. There are some studies that have indicated reduced mortality and morbidity in hypertensive subjects who receive medical treatment,[18] but an association between diuretic use and arrhythmias has been reported.[19–21] Whether the use of these agents with diabetic subjects truly predisposes to death cannot be determined from these analyses. However, it is probably wise for clinicians caring for such patients to be especially attentive to blood chemistries. Also, it has been suggested that the use of diuretics in patients with diabetic nephropathy may accelerate that condition.[22]

In these analyses we evaluated a possible relationship of mortality to use of tolbutamide. This drug had been implicated as a cause of increased mortality in the University Group Diabetes Program.[23] Its use was relatively infrequent in our study population (Table 2); it did not contribute significantly to describing mortality. □

The Accuracy of the National Death Index When Personal Identifiers Other than Social Security Number Are Used

Brent C. Williams, MD, MPH, Lucy B. Demitrack, BA, and Brant E. Fries, PhD

ABSTRACT

This study analyzed the accuracy of the National Death Index when personal identifiers were used that included or excluded Social Security number. Computerized records of the Department of Veterans Affairs were used for comparison. Different combinations of identifiers other than Social Security number correctly identified from 83 to 92 percent of dead and 92 to 99 percent of living persons. These results should prove useful in ascertaining the mortality status of patient populations without information on Social Security numbers. (*Am J Public Health.* 1992;82:1145–1147)

Introduction

Accurate determination of mortality among subjects is critical for many types of research. To meet this need, the National Death Index has been established as a national computerized database of death records compiled by the National Center for Health Statistics.

Several studies have examined the accuracy of the National Death Index,[1–10] but all were completed during its first few years of operation, and few have focused on the comparative accuracy of different combinations of information that include or exclude Social Security number in correctly establishing death. Yet, for some populations information on Social Security number is not readily available. The usefulness of the National Death Index in determining the vital status of such groups depends on the accuracy of the matching process using information other than Social Security number.

We had the opportunity to compare the accuracy of the National Death Index using information that includes or excludes Social Security number during a study of health services use among users of facilities of the Department of Veterans Affairs.

Methods

The National Death Index

Details of the National Death Index application and matching process have been described elsewhere.[1,3,5] Briefly, the index contains information from all death certificates on file in state vital statistics offices since 1979, including decedents' names, Social Security numbers, dates of birth, and several demographic characteristics. A National Death Index user may specify which year(s) of death should be searched. Records are available for searches approximately 12 to 15 months after the end of a given calendar year. After approval and upon receipt of identifying information from the investigator, all cases from the National Death Index files that meet one or more of 12 selection criteria are appended and returned to the investigator for evaluation. The selection criteria have been described elsewhere[3] (and are available from National Death Index, Division of Vital Statistics, National Center for Health Statistics, 6525 Belcrest Road, Room 840, Hyattsville, MD 20782).

Data Sources and Variables

Data for our submission to the National Death Index were compiled from computerized hospital and nursing home records of all residents of Department of Veterans Affairs nursing homes between October 1986 and April 1987. Among other data requested, information for two groups of persons was submitted: (1) a random sample of persons recorded as dying in Department of Veterans Affairs hospitals or nursing homes through October 1, 1988 ("known dead," n = 500), and (2) all persons discharged alive or who received a clinical assessment in a Department of Veterans Affairs nursing home between September 15, 1988, and October 1, 1988 ("known alive," n = 3487). These data were matched with records from the National Death Index for the years 1986 through 1988, excluding index records with dates of death after October 15, 1988.

Analytic Methods

Department of Veterans Affairs records were assumed to reflect accurately patient mortality status. The analysis was

TABLE 1—Accuracy of Patient Identifiers in Ascertaining Death from the National Death Index

Identifiers	Identifiers Alone, %		Identifiers and Social Security Number, %	
	Sensitivity[a] (n = 500)	Specificity[b] (n = 3487)	Sensitivity[a] (n = 500)	Specificity[b] (n = 3487)
FI, LN, DB, MB, YB	83	99	83	99
FI, LN, DB, MB	85	97	85	99
FI, LN, MB, YB	88	93	88	99
FI, LN, YB	90	93	89	99
FI, LN, YB or LN, DB, MB, YB	92	92	92	99
Social Security number	...	...	97	99

Note. FI = first initial; LN = last name; DB = day of birth; MB = month of birth; YB = year (±1 year) of birth.
[a]Percentage of persons "known dead" with one or more National Death Index records that match on specified criteria.
[b]Percentage of persons "known alive" with no National Death Index records that match on specified criteria.

designed to determine the "sensitivity" and "specificity" of the National Death Index for ascertaining patient mortality. Sensitivity refers to the percentage of records of persons who were known dead that had at least one matching National Death Index record for a given set of identifiers. Specificity refers to the percentage of records of persons known alive that had no matching National Death Index records for a given set of identifiers. Sensitivity and specificity are collectively referred to as "accuracy."

A match on Social Security number was defined to occur if eight or nine digits were identical in the Department of Veterans Affairs and National Death Index records. A match on year of birth occurred if the two records differed by at most 1 year, an assumption that has been shown to improve the accuracy of matching.[5]

Results

Table 1 shows the accuracy of several combinations of identifiers in ascertaining the mortality status of members of our population, including or excluding Social Security number. Based on name and birth date alone, from 83% to 92% of known decedents and 92% to 99% of persons known to be alive were identified. The matching combination with the highest sensitivity (92%) was either (1) first initial, last name, and year of birth or (2) last name and complete (day, month, and year) date of birth. For investigators without Social Security number information, this combination would identify the greatest proportion of deaths with an acceptably high specificity (92%).

Among the known dead, the vast majority of "true" matches based on name and date of birth also matched on Social Security number. Thus, including information on Social Security number did not change the sensitivities substantially. However, of the observations from the known alive group that matched on name and birth-date identifiers, a substantial portion did not match on Social Security number. This was due to a relatively large number (n = 131) of (probably false) matches only on first initial, last name, and month and year of birth, and not on Social Security number. Including Social Security number as a matching criterion therefore significantly decreased the number of false-positive matches.

Social Security number alone had the best accuracy of any combination of identifiers examined, with a sensitivity of 97% and a specificity of 99%. The improved sensitivity of Social Security number alone over any other combination of name and birth-date identifiers was largely due to 13 cases among the known dead that (probably truly) matched on Social Security number and exact birth date, but not on last name. Matching on Social Security number alone thus yielded the highest number of true matches.

Adding information on race and/or marital status to the optimal combination of variables based on name and birth date did not significantly improve the overall results.

Discussion

These results demonstrate that among patient identifiers other than Social Security number, either first initial, last name, and year of birth or last name and full date of birth provides optimal ascertainment of death using the National Death Index. Matching on Social Security number alone, however, provided the best overall results. Therefore, investigators who wish to use the National Death Index to determine the vital status of a study population should include information on Social Security number whenever possible. If this is not possible, however, the National Death Index remains a highly accurate and useful resource and will correctly identify the mortality status of at least 92% of individuals using the criteria applied in this study.

Our estimates of the sensitivity and specificity of the National Death Index using identifiers other than Social Security number are probably conservative, for two reasons. First, inevitable misclassification of patients' mortality status in the Department of Veterans Affairs data would result in falsely low estimates. Second, the Department of Veterans Affairs data include only first initial rather than first name; complete information on first name would probably improve the specificity of the results without substantially decreasing the sensitivity.

This study had two important limitations: our data included few women and did not allow stratification of the results by race. Other studies[2,8] have suggested that the National Death Index may be less accurate for women and racial minorities than for other groups. The generalizability of these results to women and minorities should therefore be evaluated in future studies. □

Race and Sex Differences in Mortality following Fracture of the Hip

Steven J. Jacobsen, MD, PhD, Jack Goldberg, PhD, Toni P. Miles, MD, PhD, Jacob A. Brody, MD, William Stiers, PhD, and Alfred A. Rimm, PhD

ABSTRACT

This paper describes the all-cause mortality experience, following a fracture of the hip, of 712 027 persons covered by the Medicare program from 1984 through 1987. White women experienced the lowest mortality rate (17.2 per 1000 person-months), followed by Black women (22.9 per 1000 person-months), Black men (33.5 per 1000 person-months), and White men (33.7 per 1000 person-months). The observed race-sex differences in survival were found at all ages and regardless of the number of comorbid conditions listed with the discharge diagnosis. While these data demonstrate marked race-sex differences in survival following hip fracture, the cause of these differences is not immediately apparent and demands further investigation. (*Am J Public Health.* 1992;82:1147–1150)

Introduction

Fracture of the hip represents a tremendous burden to the population aged 65 years and older.[1] White women experience the highest incidence of fracture, followed by White men, Black women, and Black men.[2–4] Following fracture, persons are at a much greater risk of death compared to the general population.[5–17] However, most studies of survival have been conducted in Scandinavia[6,11–13] and other predominately White populations,[14–16] and it is not known how well they generalize to the entire United States population or to minorities. The few studies that have included Blacks have been severely limited by a small sample size. The purpose of this study is to provide stable estimates of the survival following hip fracture of more than 700 000 Whites and Blacks aged 65 years and older in the United States.

Methods

Data for this study were obtained from the Health Care Financing Administration (HCFA) and have been described in detail elsewhere.[4,18,19] Briefly, HCFA maintains a computerized database of all hospital discharges covered by the Medicare program in the Medicare Provider Analysis and Review (MedPAR) file.[20] These data, keyed by Social Security Number, include the patient's age, race, and sex; up to five discharge diagnoses; zip code of residence; and dates of admission and discharge. To ascertain a date of death, records are cross-tabulated against death records from the Social Security Administration on a quarterly basis for two years following the date of admission; this follow-up information is incorporated in the summary file.

In the 1984 through 1987 MedPAR files, potential cases of hip fracture were identified as any individual with an ICD9-CM code[21] of 820.0 through 820.9 in any of the five fields provided for diagnoses (n = 810 949). Cases were excluded if age was less than 65 years (n = 19 899), if the fracture was the second or subsequent hip fracture during the four years (n = 54 055), if race was coded as other or unknown (n = 24 269), or if the fracture may have been secondary to neoplastic disease or the primary discharge diagnosis was for late effects of hip fracture (n = 4464). After exclusions, a total of 712 027 cases of hip fracture remained. (Some cases were excluded for more than one reason.)

The survival experience of persons following fracture of the hip was quantified

FIGURE 1—Observed and expected race- and sex-specific survival following fracture of the hip, all ages combined.

using mortality rates and survival function estimates. Follow-up (measured in person-months) was started on the date of admission and continued until death or censoring (January 1 of the second year following admission or 24 months, whichever was shorter). Mortality rates were calculated by dividing the number of deaths within a stratum by the stratum-specific person-time denominator[22]; survival functions were estimated using the Kaplan-Meier method.[23] Expected mortality rates within sex- and race-specific stratum were calculated[24] using the 1-year age-specific 1980 Decennial Life Table Estimates.[25]

Results

During the study period there were 687 817 discharges for hip fracture among Whites and 24 210 among Blacks (Table 1), accounting for a total of 10 270 127 person-months of follow-up. Men experienced the highest mortality, with nearly identical rates among Blacks and Whites. Rates among women were markedly lower than men, with White women experiencing lower mortality rates than Black women. The survival curves for Black women and White women diverged from the first through ninth month following fracture, thereafter remaining parallel (Figure 1). Regardless of race, men fared much worse than women.

Among all four race- and sex-specific strata, survival during the first two months following fracture was much worse than we expected, whereas from six months and onward the survival curves roughly paralleled expectations. Although mortality increased in successively older age groups among all races, the relative position of the race- and sex-specific survival curves remained constant across all age strata (Figure 2). This was also true when survival curves were stratified by the number of comorbid conditions[26] (Figure 3; see Appendix for list of comorbid conditions).

Discussion

In this study we report the survival of 712 027 Whites and Blacks aged 65 years

and older who suffered a hip fracture. Mortality was the greatest during the first 2 months following fracture but paralleled that of the general population after 6 to 9 months. In general, women survived longer than men and Black women fared relatively worse than their White counterparts. Two studies[15,17] reporting survival among Black women found them to fare worse than White women, whereas one reported better survival.[16] However, none of these studies could examine racial differences among men.

Although the observed differences are striking, potential biases must be considered when interpreting these data. The rates for Whites are consistent with previously reported results both within the United States[5,8-10,14-17] and in Europe.[6,11-13] Because race is determined prospectively, systematic miscoding of race conditional on longevity seems highly unlikely. Further, under-reporting of deaths among Blacks would tend to close the racial gap in survival. A lag in reporting time is an unlikely explanation for the differences between Blacks and Whites because the relative position of the race- and sex-specific survival curves is similar for the first six months of 1984 and last six months of 1986 (data not shown). The potential underascertainment of hip fractures[27] by relying solely on the Medicare Part A data would not explain the differences unless there was a differential under-reporting on the basis of both race and survival, which seems unlikely.

Because bias does not seem to be responsible for the poorer relative survival among Black women, etiologic causes must be sought. In contrast to mortality, the incidence of fracture among Blacks is lower than Whites[2-4]; this has been attributed to greater bone mass[28-31] and an increased prevalence of obesity.[32] Consequently, a Black person with a hip fracture may be sicker and lose proportionately more bone mass than a White person with a hip fracture. However, stratification by number of comorbid conditions suggests that the observed differences may not be due to differences in burden of morbidity. (This conclusion is limited by our measure of comorbidity, which included only diagnoses from the index hospitalization, weighted all conditions equally, and did not account for pre-fracture functional status.) Alternatively, race and sex differences in survival could be due to differences in medical care utilization and delivery, either during hospitalization or subsequent to discharge.[17] These possibilities need to be investigated more thoroughly. □

Seroprevalence of HIV-1 and Hepatitis B and C in Prostitutes in Albuquerque, New Mexico

Stephen R. Tabet, MD, Darwin L. Palmer, MD, William H. Wiese, MD, MPH, Ronald E. Voorhees, MD, MPH, and Dorothy R. Pathak, PhD

ABSTRACT

A survey of persons soliciting sex in an area known to be frequented by prostitutes in Albuquerque, NM, included 43 females and 66 males. Seroprevalence rates found in this population-based study were as follows: human immunodeficiency virus type 1 (HIV-1), 3%; hepatitis B, 39%; hepatitis C, 45%. Increased age, intravenous drug use, and condom use were independent risk factors for hepatitis B. Female gender and intravenous drug use were independent risk factors for hepatitis C. Neither sharing injection equipment nor engaging in receptive anal intercourse was independently associated with hepatitis B or C. (*Am J Public Health.* 1992;82: 1151–1154)

Introduction

Prevalence rates of human immunodeficiency virus type 1 (HIV-1) infection in female prostitutes in the United States have been reported to be as high as 58 percent.[1,2] These prostitutes' risk of infection is probably associated more with intravenous (IV) drug use than with sexual activity.[3,4] Male and female prostitutes have high rates of hepatitis B (HBV) infection.[5] Hepatitis C (HCV) rates in prostitutes are not well known, but a high prevalence in IV drug users has been documented.[6,7] Although transmission patterns for human lymphotropic virus types I and II (HTLV I/II) are unclear, the prevalence in 1305 female prostitutes in the United States was almost 7%.[8]

Most published surveys of prostitutes have been subject to selection bias because prostitutes were sampled at clinics, prisons, or treatment programs. The current study minimized such bias by sampling all street prostitutes in a circumscribed area known to be frequented by prostitutes.

The purpose of this study was to assess risk behaviors and to quantify the prevalence of HIV-1, HBV, HCV, syphilis, and HTLV I/II in street prostitutes and others soliciting sex.

Methods

In July and August of 1990 we contacted all persons who appeared to be soliciting clients for sexual activity in a geographically defined area known to be frequented by prostitutes. Subjects were offered $20 to be interviewed and provide an anonymous blood sample. A standard questionnaire was used and one investigator (S.R.T.) was always present. Test results and posttest counseling were made available through street outreach and the public sexually transmitted disease (STD) clinic.

HIV-1 antibodies were detected by enzyme immunoassay and confirmed by immunofluorescence assay. HBV infection was assessed by core antibody-IgG (HBcAb) and surface antigen (HBsAg). Antibodies to HCV and HTLV I/II were detected by enzyme immunoassay. The micro-hemagglutination assay was used for *Treponema pallidum* antibodies.

Individuals were classified as prostitutes if they reported having ever received money or drugs for sex. Condom use was assayed by reported use during any sexual activity in the previous month.

All analyses were carried out with the EGRET statistical package.[9] Odds ratios and confidence intervals for univariate and multivariate effects were estimated by logistic regression.[10]

Results

Of the 120 persons approached, 109 (91%) agreed to participate. All accepted voluntary HIV-1 testing and counseling. Participant characteristics are shown in Table 1. Although all participants were soliciting sex, only 73% reported doing so to receive money or drugs. All reported clients were male. One third of the male prostitutes behaved and were dressed as women at the time of interview. Most study participants expressed great concern about their health status, especially

the risk of HIV infection, and responded enthusiastically to education.

Three persons had antibodies to HIV-1. Two were Hispanic homosexual males who reported engaging in receptive anal intercourse; one of these also reported intravenous (IV) drug use. Both had antibodies to HBV, but not to HCV. The third person who was HIV-positive was a non-Hispanic white female prostitute who used IV drugs and had antibodies to HBV and HCV.

Fifty-eight percent of the study participants had antibodies to either HBV or HCV; 42% were negative for both. Of all participants, 14% had antibodies to HBV only, 20% had antibodies to HCV only, and 25% had antibodies to both. Seven percent had detectable HBsAg. Individuals reporting IV drug use had HBV and HCV rates of 46% and 64%, respectively. Eight (8%) had antibodies to syphilis. Two persons had antibodies to HTLV I/II (but not to HIV-1).

Table 2 shows the univariate associations of various factors with hepatitis antibodies. Variables associated with both HBV and HCV included increased age, female gender, and IV drug use. Individuals reporting IV drug use were 45 times more likely to have HCV antibodies than were those reporting non IV drug use. Of the 19 study participants who were younger than 20 years of age, none showed infection with HBV; one had antibodies to HCV. Females were six times more likely than males to have HCV antibodies. HCV was associated with both prostitution and increased number of sexual partners per night. Seropositivity to HBV was related to reported condom use. Neither ethnicity nor sharing needles was significantly related to HBV or HCV. Receptive anal intercourse was not associated with HBV or HCV infection. To test the independence of significant univariate associations, we used a stepwise logistic regression model (Table 3). Increased age, IV drug use, and reported use of condoms were independent risk factors for antibodies to HBV. For HCV, IV drug use and female gender were independent risk factors.

The effect of female gender on HCV infection was evaluated separately for IV drug users and nonusers. The odds ratios were 6.9 (95% CI = 1.7, 27.6) and 4.4 (95% CI = 0.3, 79.7) for drug users and nonusers, respectively. Thus, female gender remained significant only for IV drug users.

Condom use was compared for those older and younger than 25 years of age; the positive association of condom use with HBV remained significant only in those older than 25 years.

Discussion

The HIV-1 seroprevalence rate in this population was surprisingly low (3%), especially when compared with the 27% seroprevalence rate in homosexual men attending the local public STD clinic (New Mexico Department of Health, Office of Epidemiology, unpublished data, 1991). The relatively high prevalence of HBV and HCV allowed us to analyze risk factors known to be associated with HIV-1 transmission.

IV drug use was strongly associated with HBV and HCV infection. However, we found no significant association between self-reports of sharing injection equipment and HBV or HCV infection. An analogous lack of association between reported use of shared equipment and HIV infection has been documented.[11,12] Responses to questions about shared injection equipment may be unreliable because of reluctance to admit this behavior and because of ambiguous definitions of "sharing."[3]

Unexpectedly, reported use of condoms was positively associated with HBV infection, as has been previously observed,[13] though this association was statistically significant only for those older than 25 years of age. We speculate that high rates of *current* condom use may be associated with *past* high-risk behavior or exposures.

That receptive anal intercourse was not associated with HCV infection in our study sample is not surprising. Most published surveys suggest that HCV is inefficiently transmitted sexually, compared with HBV and HIV.[6,14,15] The lack of association between receptive anal intercourse and HBV is unclear. Self-reports of sexual activity may be unreliable; also, infection may have occurred prior to the period for which the behavior was assessed.[6]

Age was an important risk factor for HBV, reflecting the cumulative effect of risk behaviors. Female gender remained a risk factor for HCV. Subjectively, it

appeared that female IV drug users had more needle-sharing partners than did males.

The population we studied is characterized by alarming rates of behaviors associated with transmission of infectious diseases, as evidenced by the 58% seroprevalence of HBV, HCV, or both. The current low rate of HIV-1 infection in this group signals an opportunity for preventive intervention. Historically, prostitutes and IV drug users have been assumed to be nonresponsive to preventive efforts. In our study, however, most individuals were very responsive to information and appeared likely to attempt to protect themselves by using condoms and clean needles. The very high level of study participation (91%) of prostitutes who were approached in their work environment in-

Call for Abstracts for International Conference on Chronic Diseases and Changing Care Patterns

Organized by the Netherlands Society for Public Health and Science and the University of Amsterdam, an international conference on "Chronic Diseases and Changing Care Patterns in an Aging Society" will be held in Amsterdam, the Netherlands, June 9-11, 1993.

A broad range of multidisciplinary topics on both somatic and psychiatric chronic conditions will be addressed. In the plenary sessions, international experts will give their views on research and ongoing programs and their implications for care and policy. Keynote speakers include Dr. Trudi van den Bos, Dr. Jacob A. Brody, Dr. Alain Colvez, Dr. Robbert Huijsman, Dr. Louise J. Gunning-Schepers, Dr. Henk J. J. Leenen, Dr. John B. McKinlay, Dr. S. Jay Olshansky, Dr. Walter W. Rosser, and Dr. Lois M. Verbrugge.

For the parallel sessions, you are invited to submit abstracts on these issues: epidemiological, care, psychological and social, policy, economic, and ethical and legal.

Abstracts must be submitted before *October 31, 1992*. For further details and information on submission and format of abstracts, please write to: Dr. Trudi van den Bos or Wien Limburg, Institute of Social Medicine, University of Amsterdam, Meibergdreef 15, 1105 AZ Amsterdam, The Netherlands; fax 31 20.6912401.

Decreased Access to Medical Care for Girls in Punjab, India: The Roles of Age, Religion, and Distance

Beverley E. Booth, MD, MPH, and Manorama Verma, MD, DCH, MB, BS

ABSTRACT

Risk factors that increase the likelihood of discrimination against girls in India have not been well studied. In this study of hospitalized children in Punjab, India, girls were less likely to be in the newborn or infant age groups, to be of the Sikh religion, or to come from far away than were boys. These differences suggest that these factors are significant risk factors for denied access to medical care for girls living in Punjab, India. (*Am J Public Health.* 1992;82:1155–1157)

Introduction

Discrimination against girls in India, especially in the northern region, has been well documented.[1–6] Although lower socioeconomic status and high female sibling birth order have been associated with greater discrimination against girls,[2,6] other risk factors have been less well studied. In this paper we report on the effects of age, religion, and distance from the hospital on access to medical care in girls in Punjab, northwestern India.

Materials and Methods

Data were obtained on 2595 of the 2628 children admitted during 1987 to the Pediatric Ward of the Brown Memorial Hospital, Christian Medical College, Ludhiana, Punjab, India.

The male/female (M/F) ratio is the number of males admitted divided by the number of females admitted. Statistical analyses were performed using BMDP Statistical Software (Los Angeles, Calif) and Epi Info (Centers for Disease Control, Atlanta, Ga). The odds ratio is an estimate of the "odds," or likelihood, that a member of a particular group, compared with the reference group, will be female. Stepwise logistic regression was used to model the odds of being female, with simultaneous adjustment of three variables: (1) age (children [1 to 14 years of age], infants [1 to 12 months of age], and newborns [<1 month of age]), (2) religion (Hindu or Sikh), and (3) distance (coming from the city of Ludhiana and coming from outside the city of Ludhiana). The initial model contained all possible cross-product (interaction) terms, because for each combination, interaction was plausible because of prevailing social, economic, and cultural practices. The best-fit model was determined by elimination of nonsignificant ($P > .05$) terms, starting with the least significant interaction term, until all variables remaining were significant. The odds ratios and their 95% confidence intervals (CI) were calculated from the regression coefficients and covariance matrix of coefficients produced by the logistic model.

Results

Of the 2595 patients, 506 (19.5%) were girls, resulting in a M/F ratio of 4.13 (Table 1). The M/F ratio was highest in the newborn age group, in Sikhs, and in those coming from farthest away. The M/F ratio fell rapidly over the first few months of life, continued to decline through early childhood, and then leveled off after 4 years of age (Figure 1).

The unadjusted effects of age, religion, and distance are shown in Table 2. The likelihood of being female decreased with decreasing age and with increasing distance from the hospital, and was lower in Sikhs than in Hindus. The odds ratios determined by logistic regression are reported in Table 3 (Hindu children living in Ludhiana were set as the reference group). The Hosmer-Lemeshow goodness-of-fit χ^2 was 3.818 ($P = .873$). The final model consisted of age, religion, distance, and the interaction terms age × religion and distance × religion.

Discussion

The magnitude of restricted access to hospital care for girls shown by our data is impressive: the M/F ratio of 4.13 suggests that about three out of four girls (75%) who are ill enough to require hospitalization are denied this essential medical care simply because of their sex. Although it might be argued that the higher proportion of boys being admitted to the hospital resulted from a higher proportion of serious illness among boys, this is unlikely, be-

At the time of the study, the authors were with the Department of Pediatrics, Christian Medical College, Ludhiana, Punjab, India. Beverley E. Booth is now with the Department of Social and Preventive Medicine, Christian Medical College.

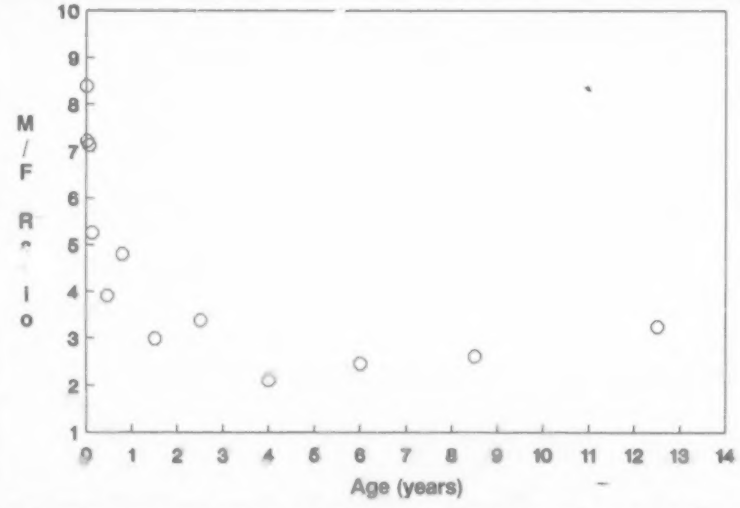
[c]The overall male/female ratio was 4.13.
[d]Compared to boys, $P < .0001$ by Student's *t* test.

cause in Punjab the infant and child mortality rates are higher for girls than for boys.[7]

The lower rate of hospital admissions for girls than for boys is congruent with social factors that result in a strong preference for sons. The presence of a dowry system, a culture in which sons inherit family land and are responsible for taking care of elderly parents, and the lesser economic worth of women, who are less well educated and less likely to work outside the home than are men, all contribute to this preference.[1]



Note. Values represent the M/F ratio of children of the following ages: 1 day, 2 to 7 days, 8 to 31 days, 1 to 3 months, 4 to 6 months, 7 to 11 months, 1 year, 2 years, 3 to 4 years, 5 to six years, 7 to 9 years, 10 to 14 years. Each group was composed of at least 123 children, including at least 21 females.

FIGURE 1—Male/female (M/F) ratio by age in children admitted to Christian Medical College, Ludhiana, 1987.

The very high M/F ratio of 7.48 in newborns admitted to the hospital must reflect these intense and complex pressures. It is a reasonable inference that these pressures lead approximately six out of seven families in the catchment area of this hospital to deny hospital admission to newborn girls ill enough to require hospitalization. The rapid decline in the M/F ratio during the first few months of life suggests that the emotional bonding between an infant girl and her family in the first weeks of life might override the factors that prevent families from seeking appropriate medical care for newborn girls.

A profound effect of distance from the hospital on access to medical care for girls is also demonstrated in the present study. Distance from a health facility is a substantial barrier to receiving medical care for anyone, but this may be especially true for children who live in a state such as Punjab, in which civil strife often makes travel difficult, uncertain, and unsafe. In addition, cultural mores in Punjab dictate that women should not travel unaccompanied even in untroubled times. Hence a trip to the hospital may represent a substantial consumption of limited resources in terms of money and work time lost for adult male relatives who must accompany the child.

In this study, hospitalized girls were less likely to be Sikhs than were hospitalized boys; however, this finding was primarily true for children who were younger than 1 year of age and for those who came from outside Ludhiana. It is possible that the admission of fewer Sikh girls from outside Ludhiana, compared with Hindu girls from outside Ludhiana, might in fact be a function more of accessibility than of religion. In Punjab, Sikhs are more likely to live in villages, whereas Hindus are more likely to live in cities, where transportation systems are better.

This study demonstrates that for girls in Punjab, young age, increasing distance from the hospital, and Sikh religion decrease access to hospital care. To redress discrepancies in access to medical care, local health workers might be instructed to make more frequent visits to homes with girls in high-risk categories. Studies are under way to determine the role that emotional attachment of the caretaker to the infant might play in determining access to medical care for girls in Punjab. If attachment turns out to be an important factor, then health workers can be trained to detect infant girls who

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc, 1015 Fifteenth St, NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50 000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health,* 1015 Fifteenth St, NW, Washington, DC 20005.

Information on Manuscript Preparation is published monthly in the Journal. The Journal publishes reports of original research, research methods, program evaluations, analytic reviews, including health policy analysis, and reports for special departments. A paper is considered with the understanding that it or its essential substance neither has been published nor is under consideration elsewhere.

Subscription price, individual, is $100/year US, $140/year international; **institutional,** $160/year US, $200/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to *American Journal of Public Health,* 1015 Fifteenth St, NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Schultz, Advertising Manager, APHA, 1015 Fifteenth St, NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St, NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols 1 to present are also available on microfilm.

Communitywide Smoking Prevention: Long-Term Outcomes of the Minnesota Heart Health Program and the Class of 1989 Study

Cheryl L. Perry, PhD, Steven H. Kelder, MPH, David M. Murray, PhD, and Knut-Inge Klepp, PhD

ABSTRACT

Objectives. The Class of 1989 Study is part of the Minnesota Heart Health Program (MHHP), a populationwide research and demonstration project designed to reduce cardiovascular disease in three educated communities from 1980 to 1993. This paper describes an intensive, school-based behavioral intervention on cigarette smoking, comparing long-term outcomes in one of the intervention communities with those in a matched reference community.

Methods. Beginning in sixth grade (1983), seven annual waves of cohort and cross-sectional behavioral measurements were taken from one MHHP intervention community and its matched pair. All students in each community were eligible to participate (baseline n = 2401). Self-reported data collected at each period described prevalence and intensity of cigarette smoking.

Results. There were no differences at baseline for either weekly smoking prevalence or intensity of smoking. Throughout the follow-up period, however, smoking rates as determined by these measures were significantly lower in the intervention community: 14.6% of students were weekly smokers at the end of high school compared with 24.1% in the reference community.

Conclusions. These results suggest that multiple intervention components such as behavioral education in schools, booster programs to sustain training, and complementary communitywide strategies may all be needed for lasting reductions in adolescent tobacco use. (*Am J Public Health.* 1992;82:1210–1216)

Introduction

Despite repeated disease warnings and some decline in the prevalence of cigarette smoking over the past 15 years, about 29.4% of the 1990 American high school graduates are current smokers.[1] They have acquired a pernicious habit that is difficult to give up and that has been described as the No. 1 cause of premature morbidity and mortality in the United States.[2] The peak time of smoking onset occurs in early adolescence, sixth to ninth grades,[3] when behavioral choices are complicated by biological, emotional, cognitive, identity, and social changes. The initiation of smoking, then, is embedded in these changes, which should be monitored and guided by the adult society.

Efforts to prevent the onset of cigarette smoking have been targeted primarily at the individual adolescent through school-based programs. These programs teach young adolescents the skills they need both to resist the social influences to smoke and to perform more general social competencies.[4,5] However, while the results of more than 20 research studies permit optimism that these approaches can delay onset of cigarette smoking, none has demonstrated positive outcomes after 3 years. Recently, several investigators have begun to add intervention components that explicitly target the social environment to aid adolescents in remaining nonsmokers.[6–9]

The Class of 1989 Study was designed to test the efficacy of a smoking prevention program that is part of a larger effort to reduce heart disease in whole communities. It is a substudy of the Minnesota Heart Health Program (MHHP), a populationwide, community-based cardiovascular disease prevention program funded by the National Heart, Lung, and Blood Institute over a 13-year period (1980 to 1993).[10] In the MHHP, the entire population in three participating cities in the north-central United States received a 5-year educational program encouraging healthy changes in eating, exercise, and smoking patterns to control high blood pressure. Three similar cities, also in the north-central portion of the United States, served as reference communities.[11] The Class of 1989 Study evaluated the youth education portion in two MHHP communities.

It was hypothesized that the effects of a school-based smoking prevention program (the Minnesota Smoking Prevention Program) with young adolescents would more likely be maintained if the program was part of 5 years of behavioral health programs in the schools and if these programs were implemented in communities where (1) adults were involved in risk factor screening and mass smoking cessation, (2) new smoking ordinances at school and in the community were being considered, and (3) multiple complementary school and community programs were established.

Methods

Research Design

The research design of the Class of 1989 Study was determined largely by the

parent project, the MHHP. Two of the six MHHP communities were involved. The community made up of Fargo and West Fargo, North Dakota, and of Moorhead, Minnesota, was one of the three MHHP intervention communities, and it received an extensive communitywide intervention program designed to improve eating, exercise, and smoking patterns across the entire population. The youth smoking prevention program was one component of that communitywide effort. Sioux Falls, South Dakota, was the reference community matched to the Fargo-Moorhead intervention community for size, socioeconomic makeup, and distance from Minneapolis–St. Paul, Minnesota. There were no MHHP-sponsored education programs for either youth or adults in Sioux Falls.

The Class of 1989 Study was established on a quasi-experimental[12] basis to assess the net effect of combining a behavioral health education program in school with the communitywide MHHP on the youth living in the intervention community. All sixth graders enrolled in the public schools in both communities were invited to participate in a baseline survey in April 1983, and that grade cohort was surveyed annually each April until its graduation from high school in 1989. From 1983 to 1986, 13 grade schools participated in the survey; and from 1987 to 1989, participating students attended 7 high schools. All students in the grade cohort were eligible to participate in each annual survey regardless of their prior participation in either the Class of 1989 surveys or the MHHP education programs, or of how long they had resided in the community. Thus, each annual survey represented a cross-sectional sample of all students in each community for the appropriate grade. By recording identifying information at each survey, it was possible to analyze the data both as specific for a cohort and as representative of a series of cross-sectional surveys using all respondents. Cohort data, using only those respondents present at baseline and at subsequent surveys, provide the strongest basis with which to test the continuing effects of the interventions. While cross-sectional data may better reflect the secular trend, they also represent students new to the area who have not received the full treatment.

During this same period, the students in the Class of 1989 study intervention community participated in MHHP-sponsored behavioral health programs in school from 1983 to 1987. Smoking prevention programs, based on the social influences model, were implemented in 1983, 1984, and 1985. Details on all the interventions of the Class of 1989 Study and of the social influences model are described in detail elsewhere.[6,13]

The primary smoking intervention, the Minnesota Smoking Prevention Program, was implemented in 1984, the fall of seventh grade. This program addresses the prevention of tobacco use by influencing the social and psychological factors that encourage the onset of smoking. First, the students begin by identifying the short-term consequences of smoking, such as smelling like smoke or having bad breath. This generally is done through small group discussions so that the consequences are relevant to the age group. Second, the students discover that smoking is not a normative behavior for young adolescents; they do this by comparing their expectations of how many of their peers smoke with actual data and by discussing their overestimates of prevalence. Third, the reasons why adolescents smoke tobacco are explored—for example, a desire to have fun, a way of making friends, a signal of maturity, or a method of coping with personal problems[14]—and positive alternatives to achieve the same goals are provided. Fourth, the students learn how these associations are established in our culture through both advertising and peer and adult role models. The methods advertisers use to convince adolescents of tobacco's functional values are presented through discussions of selected advertisements. Mock social situations are analyzed to identify the type of influences that exist. Fifth and most important, the students learn and practice skills to resist these social influences to smoke. They create anti-tobacco advertisements and skits (role playing) around possible social encounters. Sixth, near the end of most programs, the students make a public commitment to abstain. This commitment acts as a psychological anchor and explicitly creates an intention not to experiment with substances. Finally, all these activities are experiential—designed to require active participation—and often are led by trained peer (same-age) leaders, who have proven to be effective communicators for many of the social and psychological messages intrinsic to the program.[15]

In addition to the school-based intervention, the intervention community participated in the MHHP populationwide intervention. Indirectly, the students received this intervention over a 5-year period through a deliberate attempt to restructure the adult social and physical environment with regard to heart-healthy behaviors and values.[10,11] The primary intervention components of the MHHP included seven strategies: (1) population-based risk factor screening for cardiovascular disease, in which more than 60% of adults participated in a 1-hour health assessment and direct education program for healthy eating, exercise, and smoking; (2) grocery and restaurant heart-health point-of-purchase food labeling education; (3) community organization and citizen task forces to develop annual risk factor education campaigns; (4) continuing education of health professionals to promote understanding of the nature of cardiovascular disease risk and prevention; (5) mass media education via television, radio, newsprint, etc.; (6) adult education in work sites, churches, workshops, and other organizations; and (7) youth education.

Outcome Evaluation

Outcome evaluation was conducted through an annual survey in all the school districts in the two communities from March to April of 1983 to 1989. The survey instrument was derived from a cognitive-behavioral model and the needs assessment surveys in each community.[13,16] Administered by survey staff from the MHHP who were trained for classroom administration, the survey took approximately 40 minutes and was completed by the students in their health, social science, or English classes. All students in the relevant grade level who were present on a particular day were tested.

The measures for tobacco use—the focus of this paper—each year included self-reported smoking history and, in 1986 only, the amount of thiocyanate in saliva samples. Psychosocial variables pertaining to smoking etiology were not included in this study because this question was the subject of a separate, ongoing research project and limited space was available on the survey instrument. The self-report items, standardized questions with acceptable reliability and validity, have been used in previous smoking research.[17] The prevalence of weekly smoking was used to assess the impact of the intervention. In addition, a smoking intensity score was created from the self-reported measures. Smoking intensity represents the number of cigarettes smoked per week by each student, calculated as an average of three self-report questions related to daily smoking, weekly smoking, and smoking history. The method of calculation of

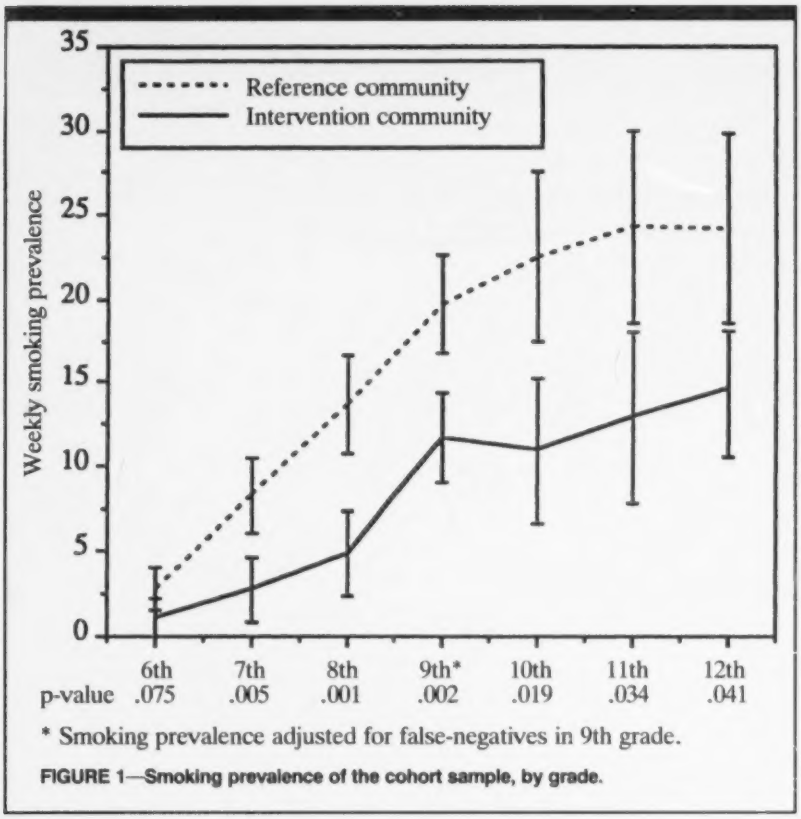

FIGURE 1—Smoking prevalence of the cohort sample, by grade.

smoking intensity has been described in detail elsewhere.[17] Test-retest correlation for smoking intensity from this age population was .99.[17]

Saliva samples were obtained for biologic validation of self-report in 1986 with a random sample of half the classrooms (n = 1076 students); this was done with dental cotton rolls, which were held in the mouth for 5 minutes. The amount of saliva thiocyanate (SCN), a byproduct of smoking tobacco, was collected and determined by methods described elsewhere.[17,18] The correlation of smoking intensity with SCN was 0.46 ($P < .0001$), a value not unexpected considering that student smoking habits at this age are sporadic. SCN is a useful measure in this situation primarily to identify false-negative self-reports (i.e., self-reported nonsmokers with an SCN value indicating smoking status) and is less likely to classify false-positive self-reports (self-reported smokers with a low SCN value) correctly. SCN values were used in these data to correct false-negative self-reports in 1986 using a cutoff point of 79 μg/mL derived from internal data as described by Cummings and Richard[19]; this accounts for low levels of SCN due to passive smoking.

Other relevant measures are age at the time of survey, sex, and parental occupation. Questions related to parental occupation were added in 1987 and are used to produce an index of household occupation in which 1 = both parents are white-collar workers, 2 = both parents are clerical workers, 3 = both parents are blue-collar workers, and 4 = parents are mixed as to the three categories. Single parents were coded for their occupation.

Analysis Methods

This study combines elements of what we have termed *nested cohort* and *nested cross-sectional* designs.[20] In these designs, intact social groups (e.g., whole cities) are assigned to conditions. In the nested cohort design, subjects within those groups are followed over time as a cohort to assess the effects of the interventions. In the nested cross-sectional design, independent samples of subjects within those social groups participate at each measurement occasion. In either design, subjects from a single community will tend to be more like one another than they are like subjects in other communities. This within-community correlation in the data, indexed by the community-level intraclass correlation coefficient (ICC), adds an additional component of variability to the intervention group means above and beyond that attributable to either the individual subjects or the interventions themselves.[21] Unless this component is accounted for in the analysis, the evaluation of the intervention effects will be positively biased in proportion to the magnitude of the ICC and the number of respondents in each community.[22]

Note that in the present study, students were observed in classrooms, which were nested within schools, which were nested within the towns assigned to the two treatment conditions. Fortunately, ICC, which reflects the within-unit correlation in the data at each level of nesting, also captures the within-unit correlation at all levels of nesting lower in the hierarchy. Thus, while we could not use the community as the unit of analysis, we could correct for most of the variance inflation expected in such a design by using instead the next level in the hierarchy: the school. This was accomplished for the data gathered after 1985 using PROC GLM in SAS,[23] in which a model that used the individual's smoking status as the outcome and included school as a nested random effect was fit for each round of data; the intervention effect was tested against the school variance. The school identifier was not available in the data collected for elementary schools prior to 1986, and so the school variance was estimated by standard methods using schools from subsequent years.[20,21] Separate analyses were performed for each follow-up round. For the cross-sectional analyses, all participants were included; for the cohort analyses, only those who also participated in the baseline survey were included. All analyses included covariance adjustments for age and sex, and in the years 1987 to 1989, adjustments were made for parental job class.

Results

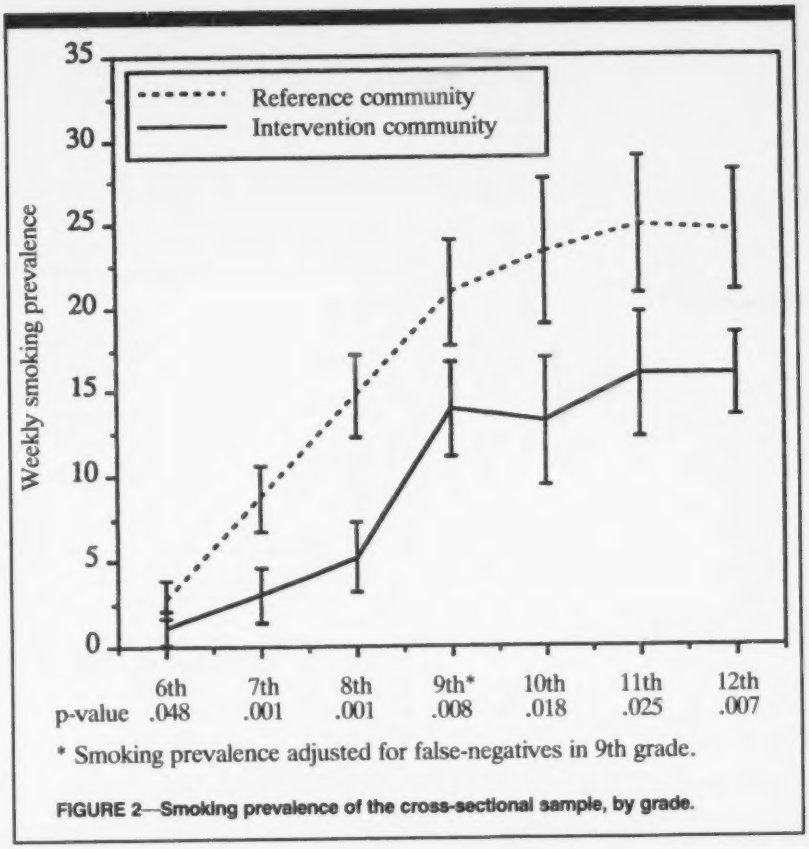
Smoking Outcomes

The cross-sectional and cohort smoking outcome data were analyzed to examine differences between communities in both the percentage of weekly smokers and the smoking intensity for each year from 1983 to 1989. No significant differential program effects were observed between the sexes, so the results for the two sexes were pooled for presentation purposes. Figures 1 and 3 present the results from the cohort analyses for

weekly smoking prevalence and smoking intensity, respectively; Figures 2 and 4 present the results from the serial cross-sectional analyses. All figures present mean levels, 95% confidence intervals, and intervention/reference comparison *P* values, adjusted for the school effects as described in the Analysis section above. The unadjusted smoking prevalence and intensity differed by less than 1%, or by one cigarette per week, respectively, for either treatment condition, and these measures offer the same magnitude of intervention effects as the covariate adjusted results.

Although no significant differences were detected at baseline (1983) in the cohort sample, Figures 1 and 3 reveal significant differences for smoking prevalence and intensity between communities for this sample at all follow-up years (1984 to 1989). At the end of high school, 14.6% of the cohort sample from the intervention community were smoking compared with 24.1% from the reference community. Similarly, Figures 2 and 4 show significant differences between communities for the cross-sectional samples at all follow-up years. Cross-sectional students represent those remaining in the community throughout the study as well as those not present at baseline or new to the community. In Figures 2 and 4 we observe only a slight increase in smoking prevalence and intensity for the cross-sectional sample as compared with the cohort sample, indicating that these students have little impact on how these trends are interpreted.

Saliva samples were obtained from a random sample of approximately half of all classrooms in 1986, with SCN analyses completed on 667 and 409 students in the intervention and reference communities, respectively. Using school as the unit of analysis, significant differences between communities were found in the SCN level, with the intervention community significantly lower than the reference community in both the cohort sample (54 vs 39 μg/mL, $P = .0002$) and the cross-sectional sample (56 vs 41 μg/mL, $P = .0009$). Note that adjustment for false-negative self-reported smoking prevalence was done in 1986 as described in the Methods section above. The number of false-negative reports verified by SCN differed by community, with 9.8% (n = 40) in the reference community claiming falsely not to be smoking compared with 6.5% (n = 43) in the treatment community ($\chi^2 = 4.3$; $P = .038$; individual unit of analysis).[18] The effect of false-negative adjustment was to raise the prev-



* Smoking prevalence adjusted for false-negatives in 9th grade.

alence estimates for both communities. This is especially noticeable in Figures 1 and 2 for the intervention community, in which a sharp increase was observed between eighth and ninth grades, most of which can be attributed to the false-negative correction.

Attrition Analysis

Table 1 presents the study sample size and follow-up by year and grade for the cross-section and cohort samples. Financial constraints precluded any attempt to contact those students who moved out of the community, were absent, were involved in work-study, or dropped out and were not in class on the day of the survey. Response rates by intervention and reference communities were nearly equal except for the last year of data collection, in which 55% of intervention cohort students were resurveyed compared with only 32% in the reference schools. Because missing students were not recontacted, we cannot estimate the extent of differential attrition on smoking, but this can be approximated by identifying the previous year's values for those students not present. Table 2 presents the previous year's smoking prevalence for students missing in the cohort sample. For example, for students not present in 12th grade, 29% in the reference community were smoking at least weekly in 11th grade compared with 23% in the intervention community. Had those identified in any previous year remained smoking in the following year, the magnitude of the intervention difference would have been increased in four of the six follow-up evaluations by 0.5% to 2.3% and would have declined in the other two by 0.2% to 0.35%. In no year would the addition of these missing students have altered the intervention group differences observed or the given interpretation of these results.

Discussion

The Class of 1989 Study was designed to take advantage of the time of transition to adolescence by using peer-led, behavioral, school-based smoking prevention programs nested within a community-based intervention. This paper describes smoking outcomes for cross-sectional and cohort samples from the intervention and reference communities for 1983 to 1989.

Smoking rates throughout the follow-up period were substantially lower in the intervention community when measured by either weekly smoking prevalence or smoking intensity. These differences were confirmed by SCN analysis in 1986. The risk of being a smoker upon graduation in 1989 in the intervention community was about 40% lower than it was in the reference community.

The results of the study should be considered in comparison with other smoking prevention studies. For the most part, the effects of other programs have diminished over time, and few investigators have reported effects past the 10th grade.[9,24,25] This suggests that behavioral education in schools, booster programs to sustain training, and complementary communitywide change may all be needed to maintain effects with young people. Since virtually all cigarette smoking is initiated prior to high school graduation, the maintenance of significant differences through 12th grade should lead to the eventual reduction of adult smoking and smoking-related diseases.

The study has several limitations. The common threats to internal and external validity associated with nonrandom assignment are well known, and several such threats pertain to this design, including baseline pretreatment differences, regression to the mean, differential maturation and attrition, and history.[12] At baseline, both smoking prevalence and intensity measures were slightly higher in the reference community. These differences at the early stages of smoking onset were small, and separate analyses of covariance in the cohort sample adjusting for these differences required no changes in

TABLE 2—Previous Year's Smoking Prevalence of Students Missing in the Cohort Sample

	Identified Missing Students, n		Weekly Smoking, %	
	Intervention	Reference	Intervention	Reference
11th grade smoking prevalence of students missing in 12th grade	211	305	22.6	28.9
10th grade smoking prevalence of students missing in 11th grade	211	124	17.8	42.4
9th grade smoking prevalence of students missing in 10th grade	147	157	23.1	31.2
8th grade smoking prevalence of students missing in 9th grade	256	148	9.4	23.2
7th grade smoking prevalence of students missing in 8th grade	134	157	3.7	15.8
6th grade smoking prevalence of students missing in 7th grade	163	135	0.0	3.0

our interpretation of these data. Differential regression is unlikely, given the multiple observations and the fact that differences were observed after baseline observation and became larger over the 7 years. Attrition over time may underestimate smoking prevalence in both communities since absent students are more likely to smoke.[26,27] Attrition analysis indicates, for most years, a bias that reduced the magnitude of the intervention effect because of higher levels of smoking in the reference community as a result of those missing at the time of measurement.

Unfortunately, differential maturation and local history are completely confounded with the series of interventions, and thus they cannot be so easily dismissed. At issue is whether the lower onset rate in the intervention community was due to some cause other than the intervention, and whether the increase in smoking in the reference community was as high as it was due to some cause other than the usual high school secular trend. Annual reviews of related community programs as well as of the existing school health programs that were done by the investigators in either community did not reveal an alternative explanation for the effects observed. In addition, smoking rates at the completion of the study in Sioux Falls are comparable to those obtained in a 1990 representative survey of high school seniors for the North Central Region, in which 22.2% reported smoking at least one cigarette per day over the previous 30 days.[1] Finally, no policy level changes in taxes or availability of cigarettes were noted to have occurred during or immediately prior to the evaluation period.

The Class of 1989 Study does, then, permit optimism for the benefits to youth of long-term, school-based, communitywide programs, and specifically for the retardation of uptake of smoking behavior. The adoption of behavioral programs across multiple communities appears to be feasible; outcomes can be sustained in a supportive environment. The communities selected for this study represent typical middle-size midwestern communities, and the results should be generalizable to similar settings. Examination of these school-based, communitywide approaches appears to be warranted for youth with other high-risk social and health behaviors, and especially for youth in lower socioeconomic communities, where these problems are more acute and existing resources are scarcer. The need for research in these populations is clearly critical. □

Public Health Policy Forum Submissions Invited

The "Public Health Policy Forum," a new feature of the Journal, is intended to provide a presentation of divergent views on important public health policy issues that is more extensive than the Journal's format usually allows. Three kinds of material will appear in the Public Health Policy Forum: articles, not to exceed 4500 words; commentaries, not to exceed 2500 words; and editorials. Customarily, commentaries and editorials will be solicited by the Journal's Associate Editor or Editor. Articles for the Public Health Policy Forum will be selected from articles submitted to the Journal and, on occasion, from those submitted directly to the Associate Editor. In general, peer review will still be sought.

Those wishing to submit articles directly to the Associate Editor may do so at this address:

Bruce C. Vladeck, PhD
The United Hospital Fund
55 Fifth Avenue
New York, NY 10003-4392

Five copies of the article should be submitted simultaneously to the Journal's Washington, DC, office.

The scholarly merit and the scientific accuracy of all submissions will be considered. Additional criteria are relevance to an important policy issue, timeliness, and clarity and coherence of the policy argument. Brevity also helps considerably.

Locking Devices on Cigarette Vending Machines: Evaluation of a City Ordinance

Jean L. Forster, PhD, MPH, Mary E. Hourigan, MPH, and Steven Kelder, MPH

ABSTRACT

Objectives. Policymakers, researchers, and citizens are beginning to recognize the need to limit minors' access to tobacco by restricting the sale of cigarettes through vending machines. One policy alternative that has been proposed by the tobacco industry is a requirement that vending machines be fitted with electronic locking devices. This study evaluates such a policy as enacted in St. Paul, Minn.

Methods. A random sample of vending machine locations was selected for cigarette purchase attempts conducted before implementation and at 3 and 12 months postimplementation.

Results. The rate of noncompliance by merchants was 34% after 3 months and 30% after 1 year. The effect of the law was to reduce the ability of a minor to purchase cigarettes from locations originally selling cigarettes through vending machines from 86% at baseline to 36% at 3 months. The purchase rate at these locations rose to 48% at 1 year.

Conclusions. Our results suggest that cigarette vending machine locking devices may not be as effective as vending machine bans and require additional enforcement to ensure compliance with the law. (*Am J Public Health.* 1992;82:1217–1219)

Introduction

It has been well established that, in the United States, the onset of tobacco use occurs during adolescence.[1,2] School-based tobacco use prevention programs have shown limited long-term effects, leading to increased attention to strategies with potential to limit adolescents' access to cigarettes.[2] Reducing access to tobacco is an approach to tobacco use prevention that is favored by the general population as well.[3,4] Since 1989, at least 50 cities in Minnesota have adopted ordinances that restrict or prohibit cigarette vending machines because of the access to cigarettes they provide to teenagers.[3,5] Other cities and states are following Minnesota's lead in restricting youth access to tobacco through restrictions on vending machines and other policies.

In response, the tobacco and vending machine industries have proposed alternative policies that are less restrictive than vending machine bans, such as requiring cigarette vending machines to be retrofitted with locking devices that prevent cigarette purchase unless the lock is deactivated by an employee. A number of jurisdictions in the United States have adopted laws that require these devices on some or all cigarette vending machines.

Very little is known about the effectiveness of locking devices in limiting minors' ability to purchase cigarettes. Industry representatives maintain that such devices make vending machine purchase of cigarettes equivalent to over-the-counter sales by placing the sale under the control of an employee. Health advocates argue that (1) locking devices require extra enforcement to ensure that the devices are installed and operating and (2) the unlocking mechanism can be placed far away from the machine or even out of sight, eliminating the face-to-face encounter with the potential purchaser. Thus, a policy requiring locking devices is unlikely to be as effective as a vending machine ban in reducing the ability of minors to purchase cigarettes.

The only long-term experience with vending machine locking devices comes from Utah, which had a state law until 1989 requiring their installation. The experience in Utah was that the devices were rarely installed (1 of 22 machines was equipped with the device in one informal study), and, where installed, they were rarely operating (B. Neiger, written communication, February 1990). The Utah law was changed in 1989 to prohibit vending machine sales of cigarettes in most locations.

St. Paul, Minn, a city of approximately 270 000 people, adopted an ordinance requiring that locking devices be installed on all cigarette vending machines in the city effective July 1, 1990.[6] This policy provided the opportunity to measure the effectiveness of locking devices in a variety of business settings to limit minors' access to cigarettes. The purpose of this study was (1) to document the compliance of businesspeople with the new ordinance at 3 months and 1 year following the effective date and (2) to measure the effectiveness of such a policy in re-

No cigarette sales	33	0	25	13

ducing the ability of minors to purchase cigarettes from vending machines.

Methods

A list of all cigarette vending machine locations was obtained from the City of St. Paul in May 1990. Both the 1989 and 1990 lists were used since the licensing procedure changed in 1990 and some locations had not yet obtained their 1990 licenses. By comparing the two lists, 237 cigarette vending machine locations were identified. A random sample of 109 of these locations was selected using a random numbers table, with the goal of collecting data from 100 locations. Locations were subsequently excluded after visitation if there was no vending machine present, if the location was a private business with no access, or if the site was closed during baseline data collection. The total number of sites for which baseline data could be collected was 95. The vending machine locations included in this study were classified into restaurants (34%), bars and liquor stores (56%), and other (other stores, hotels; 10%). Cigarette purchase was attempted at these same locations at three points in time: just before the date the law was in effect, 3 months following baseline, and 1 year following baseline. For the results presented below, we included information for only those sites that were open for business on all three occasions when they were visited for the purchase attempt, so that we could document changes over time. This reduced the number of sites to 77.

All of the purchase attempts in this study were made by one individual, a girl who turned 15 years old just before the baseline observation. At each data collection point, this same girl was taken to each study site by an adult staff member. She dressed in age-appropriate clothing with no makeup. She attempted to buy cigarettes, and was debriefed immediately upon returning to the car by the driver. Items recorded in addition to whether she was able to purchase cigarettes included the date and time of day, the type of business, the type of sale (over the counter or vending machine), whether there was a locking device on the machine and whether it was operational, and whether anyone questioned her or commented about her age. All purchase attempts were completed between 3 PM and 7 PM.

Results

Merchants could comply with the law by installing a locking device, switching to over-the-counter sale of cigarettes, or discontinuing the sale of cigarettes altogether. Table 1 shows that 3 months after the law went into effect, over a third of the locations still had cigarette vending machines without a locking device. Businesses that mainly sold alcohol were least likely to comply, and restaurants were most likely. Merchants who did comply with the law were most likely to do so by installing locking devices, but a quarter of them either decided not to sell cigarettes at all or to switch to over-the-counter sales rather than install a locking device. By 1 year after the effective date, 30% of the merchants were still out of compliance with the law.

The second question regarding locking devices concerns the effectiveness of the law in limiting minors' ability to purchase cigarettes at the study locations. As shown in Table 2, the overall purchase success rate in these locations, all of which originally sold cigarettes through vending machines, decreased from 86% before the law went into effect to 30% at 3 months after the law was enacted; it subsequently rose to 48% at 1 year after the law. Businesses that installed locking devices on their vending machines were less likely to sell cigarettes to our teenage confederate than businesses with unlocked vending machines, but businesses that switched to over-the-counter sales were the least likely to sell cigarettes to minors, of those that still sold tobacco. Cigarette sales to our confederate declined the most at sites located in restaurants. The effect of the law deteriorated over the course of the year in all types of businesses, regardless of the merchants' choice of compliance, except in those that eliminated tobacco sales.

Comments about the age of the purchaser increased during the course of the study. At baseline, an employee questioned or commented about the confederate's age during 14% of the visits. After the locking device law had been in effect for 3 months, the rate of comments or questions rose to 55%, and then declined to 40% at 1 year.

Discussion

This study provides the first information about the effects of a policy that requires locking devices on cigarette vending machines. The results indicate that compliance with locking device laws is a problem. The implementation of the law was accompanied by a great deal of media attention. In addition, information about the requirements of the law was sent by the city licensing office to all vending machine license holders, and a city licensing official inspected each licensed location soon after the law went into effect, issuing a warning when the machine was not in compliance. Thereafter, each location was to be inspected annually, at the time of license renewal. Even 1 year after the law went into effect, 30% of the vending machines in this sample did not have locking devices. In contrast, two cities that have banned cigarette vending machines altogether show complete compliance, even almost 2 years after the ban took effect.[7] These data suggest that a locking device policy places an additional enforcement burden on city officials, thus reducing the potential effectiveness.

TABLE 2—Cigarette Purchase Success by Method of Compliance with Locking Device Law and Type of Business

	Baseline		3 Months Postlaw		1 Year Postlaw	
	%	No.	%	No.	%	No.
Type of sale						
Locking device	0	1	19	32	39	36
No locking device	87	76	65	26	91	23
Over-the-counter sale only	0	0	0	7	25	8
No cigarette sales	0	0	0	12	0	10
Type of business						
Restaurant	92	24	21	24	33	24
Bar or liquor store	80	45	33	45	56	45
Other	100	8	38	8	50	8
Total[a]	86	77	30	77	48	77

[a]Comparison of purchase success at 3 time points: $\chi^2 = 50.39$ (2 df); $P < .0005$; for Time 1–Time 2 difference, 95% CI = 41%, 71%; for Time 1–Time 3 difference, 95% CI = 24%, 52%.

Businesses that switched to over-the-counter sales of cigarettes or discontinued the sale of cigarettes added to the overall effectiveness of the law. The cost of retrofitting a vending machine to comply with the law is estimated at between $35 and $100, but only electronic vending machines can be modified.[8] These factors may have influenced some businesses to eliminate the machines. The overall effectiveness reflects low purchase success at sites that complied with the law (12% success at 3 months, 30% at 1 year) in combination with high success rates at sites that did not comply (65% success at 3 months, 91% at 1 year), providing evidence that low compliance reduces the potential effectiveness of a locking device policy.

Furthermore, effectiveness depends on employees checking age identification and refusing to deactivate the device if a minor attempts to purchase from the machine. This study shows that even when the locking device is installed, employees allowed purchase by our 15-year-old confederate 19% of the time at 3 months and 39% of the time at 1 year.

This study suggests that a locking device policy results in fewer locations selling cigarettes to minors than a policy of no restriction on cigarette vending machine sales but is probably less effective than the major policy alternative, a ban on cigarette vending machines. A follow-up of former vending machine locations in a community that instituted a ban shows only 8% of those locations selling tobacco to a 15-year-old confederate at 3 months and 15% at 15 months, compared with 30% and 48% at roughly the same time points in this study.[7] The community with the vending machine ban may have less tolerance for cigarette sales to minors, which could account for some of the difference in compliance. However, both cities are located in the same metropolitan area.

This study is limited by the fact that sites are drawn from a large urban city and may not represent the mix of locations or the responses of businesses in smaller cities or suburbs. Furthermore, the pre–post comparison design does not control for possible time trends, such as an increase in enforcement of the age of sale law. Such trends are likely to exaggerate the effectiveness of the locking device policy, and our results may represent the upper limit of the effectiveness of such a policy.

Controlling cigarette sales by vending machines is only one aspect of a coordinated local, state, and national policy effort proposed by many health professionals, policymakers, and researchers.[9-11] Our experience in Minnesota suggests that restricting vending machines is often the first step for communities, and the restrictions have both substantive and symbolic value.[7] Community leaders and businesspeople reason that enforcement of existing laws or adoption of new restrictions against over-the-counter sale of cigarettes is pointless as long as cigarettes are freely available in machines that do not allow discrimination by age of purchaser. Adoption of vending machine restrictions is often the first sign that a community is ready to treat cigarettes as a controlled and potentially dangerous product. It is important that these first steps toward controlling tobacco sales produce meaningful changes in availability, and do not simply add to the list of unenforced and unenforceable laws. □

Adolescents' Multisubstance Use Patterns: The Role of Heavy Alcohol and Cigarette Use

Susan L. Bailey, PhD

ABSTRACT

Objectives. Knowledge about the roles that heavy alcohol and cigarette use play in patterns of concurrent substance use among adolescents is lacking despite studies showing that adolescent substance users are typically multisubstance users and that alcohol and cigarettes are commonly used heavily by those who use illicit substances.

Methods. The roles of increasing use and heavy first-time use of alcohol and cigarettes in multisubstance use patterns were examined in a cohort of 4192 secondary students who were surveyed three times over a 4-year period.

Results. When subsequent use patterns were compared for students who increased their levels of alcohol or cigarette use and those who initiated use for the first time but at heavy frequencies, analyses indicated that the former group was more likely to initiate the subsequent use of other substances and to maintain and increase use already initiated.

Conclusions. These results suggest that adolescents are likely to have been involved in a history of licit substance use characterized by increasing levels of use before progressing to and maintaining the use of other substances. Increasing frequencies of alcohol and cigarette use, therefore, may be markers for more serious patterns of substance use. (*Am J Public Health.* 1992;82:1220–1224)

Introduction

Studies focusing on the prevalence of adolescents' use of various types of substances have shown that substances are initiated in particular sequences.[1–7] A study conducted by Donovan and Jessor moved beyond focusing only on initiation to examine the position of heavy or problem alcohol use in the sequence of substance use among adolescents.[4] Results of their study suggest that heavy use of at least one licit substance may occur after the initiation of an illicit substance. The results of other studies suggest the importance of including heavy cigarette use when examining patterns of substance use among adolescents.[2,8–12]

Up to now, little attention has been given to the potentially different roles of heavy initiation or increasing use of licit substances or to the role of heavy cigarette consumption in general in adolescents' substance use careers. The main purpose of this analysis is to examine whether changes in levels of concurrent use of cigarettes and alcohol among youth can be used, over time, to predict subsequent substance use. In particular, this analysis evaluates whether heavy use of cigarettes and alcohol at an early point in time or increasing use of these substances over time presages more generalized substance use later on. Studies of substance use careers conclude that the longer the career, the more serious it is likely to be.[7,13] This conclusion suggests the hypothesis that increasing levels of use of licit substances during youth is more predictive of more serious patterns of use than is heavy initiation.

Methods

Subjects

The data used in this analysis were collected as part of two studies: the Study of Multilevel Substance Abuse Prevention for High-Risk Youth and the Study of Sequencing of Alcohol, Drugs, and Tobacco Among Youth. In these studies, a cohort of middle school (grades 6 to 8) students in a southeastern US county was followed through three rounds of data collection (T_1 – T_3) conducted from 1985 to 1990. Respondents were in grades 6, 7, and 8 (mean age = 12.3, SD = 0.98) at T_1; in grades 7, 8, and 9 (mean age = 13.7, SD = 1.0) at T_2, approximately 1 year after T_1; and in grades 9, 10, and 11 (mean age = 15.7, SD = 1.0) at T_3, approximately 2 years after T_2. Attrition was approximately 25% between each successive wave, and a total of 4192 students were included in all three rounds. Attrition analyses indicated that many of the substance users and heavier users included at T_1 subsequently were lost to the study. (See Table 1 for comparisons of mean levels of use at T_1 for those lost to and retained in the study.) Results reported here, therefore, are biased by the exclusion of a portion of the substance users. The results are also limited to students' self-reports of substance use. Analyses reported elsewhere, however, indicate that students were generally consistent in their reporting of use across rounds.[14] Additional details of the data are presented elsewhere.[15]

[c]Categories for these variables: 0 = no use, 1 = light use, 2 = heavy use.
[d]Categories for these variables: 0 = no use, 1 = use.

Measures

The substance use measures focused on use in the year or, for one substance, use in the month prior to the survey. Students who reported a frequency of cigarette use between at least one pack a day and a half pack to one pack a week were coded as heavy users; light users were those who smoked less than a pack a month; and others were classified as abstainers during the period of interest. Students were coded as light alcohol users if they drank only once in the past year regardless of the number of drinks consumed, or if they drank any amount up to and including two drinks on the typical occasion (i.e., two to five times in the past year up to almost daily). They were coded as heavy drinkers if they drank three or more drinks on the typical occasion. Other substance use items included in the analyses measured past year use compared with no use of inhalants, marijuana, and other illicit drugs.

Results

Changes in Concurrent Use

Percentages of students reporting concurrent substance use patterns in the year prior to each round of data collection are presented in Table 2. For each round, patterns associated with percentages greater than 1 are reported. Percentages are reported separately for males and females and are compared to determine whether patterns differ by sex and whether subsequent analyses should be conducted separately for the two groups.

A comparison of common substance use patterns for males and females shows relatively little difference at all three rounds of data collection. The most consistent and sometimes largest difference concerns the heavy use of alcohol with no other substance use. At all three rounds, males were more likely than females to report this pattern. However, alcohol used heavily and in combination with other substances does not show a consistent difference by sex: sometimes females and sometimes males were more likely to report particular patterns involving heavy alcohol use. Other differences were small and not consistent across rounds. Because there were few differences in substance use patterns between males and females, subsequent analyses were conducted for both groups combined, and results are reported for the entire sample.

Percentages calculated for the total sample and reported in Table 2 show that the most commonly reported pattern at all three data collection points was no use of any substance; however, the proportion of abstainers declined by more than 20 percentage points from T_1 to T_3. At T_1, light alcohol use was by far the most common pattern of use and was a component of all but the two least common patterns among those that met the criteria to be reported (i.e., at least 1%). In the year prior to T_2, cigarettes emerged as a substance used either alone or in combination with other substances, typically at a heavy level when more than one other substance was used. When cigarettes were used heavily, they were most commonly used with alcohol, also at a heavy level and with all other substances. By T_3, heavy alcohol use appeared in the majority of the most common patterns. As for T_2, when alcohol and cigarettes were used heavily, they were commonly used in combination with other substances. Heavy alcohol and cigarette use, therefore, appeared to play a pivotal role in multisubstance use patterns. We now turn our attention to the roles of increasing use and heavy use initiation in these patterns.

Prevalences Relative to Transitions

Transitions were measured as changes in use (i.e., initiation or increased use) between T_1 and T_2 and were indicated by comparing reports of use at T_1 and T_2. Six such transitions were examined. These were (1) initiation of light alcohol use for those who were abstinent at T_1, (2) initiation of heavy alcohol use also for those who were abstinent at T_1, and (3) increase from light use at T_1 to heavy use at T_2, as well as (4) initiation of light cigarette use, (5) initiation of heavy cigarette use, and (6) increase from light to heavy cigarette use. The transitions were not mutually exclusive. Prevalences of other types of substance use subsequent to the transition (T_3) were examined for those who experienced each transition.

Percentages of students who initiated other substances during the 2-year period subsequent to the transitions of interest are presented in Figure 1. Generally, students who increased their frequency of alcohol use prior to T_2 were more likely than those experiencing other transitions involving alcohol to initiate subsequent use of other substances (with the exception of cigarettes). Too few cases of students who increased their frequency of cigarette use prior to T_2 were available to see if this pattern also holds for transitions in cigarette use.

The percentages of students who increased or decreased their frequencies of alcohol and cigarette use after the transitions of interest are presented in Figure 2. The graphs show that students were more likely to increase than to decrease their frequencies of use during this period.

Other patterns	12.9	10.1	11.5	15.5	14.2	14.8	16.8	15.2	16.1
	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0

Note. Percentages are presented separately for each round of data collection. T_1 refers to the 1985–1986 school year for urban schools and the 1986–1987 school year for rural schools. Respondents were in grades 6, 7, and 8 during this first round. T_2 refers to the 1986–1987 (urban) and 1987–1988 (rural) school years when students were in grades 7, 8, and 9. T_3 refers to the 1988–1989 and 1989–1990 school years when respondents were in grades 9, 10, and 11.

[a]Ellipses indicate less than 1% of the sample reported the pattern. The few students who did report the pattern were included in the "Other Patterns" category so columns would add to 100%. Otherwise, patterns are mutually exclusive.

Those who increased their frequency of cigarette use by T_2 were particularly unlikely to decrease their subsequent frequency of alcohol use.

Percentages of students who quit using substances subsequent to the transitions of interest at T_2 are presented in Figure 3. Generally, students were very likely to quit using substances during this period. The graphs presented in Figure 3 also show that students who increased their use of alcohol and cigarettes by T_2 were, in most cases, the least likely to quit the subsequent use of other substances. Those who initiated at light levels of use, on the other hand, were the most likely to quit other use later. This difference holds for subsequent discon-

tinuation of the same substance initiated or used more heavily by T_2. Students who initiated alcohol at light levels of use were most likely to quit subsequent alcohol use, followed by those who initiated at heavy levels, with those who increased use being the least likely to quit. Generally, the same pattern holds for cigarette use, although heavy cigarette initiators were slightly more likely than light initiators to quit later. Students who increased their cigarette use were the least likely of all students to quit cigarette use at a later time.

Discussion

As indicated in other studies,[1–7,16] results reported in this paper demonstrate that adolescents are more likely to initiate and use substances as they progress through middle school and into high school. Our results also suggest that the transition to heavy use of alcohol and cigarettes might be an important turning point in adolescents' substance use careers. When alcohol and cigarettes were used heavily by adolescents in our study, they were most often used in combination with illicit substances. These patterns were found for both males and females.

Our results also showed that it was less the level of alcohol and cigarette use that indicated subsequent multisubstance use than it was the progression to greater frequencies of use. Students who first initiated use at high levels were less likely to use these and other substances subsequently than were those who increased their frequencies of use. Students must have been involved in a longer history of use characterized by increasing levels of use in order to continue use and to progress to using other substances. These results support those reported by others, which conclude that the longer the substance use career, the more serious it is likely to be.[7,13] To these results, we add the conclusion that progression from lighter to heavier use of licit substances during adolescence likely plays a role in characterizing more serious substance use careers.

More research is needed to determine what predicts increasing frequencies of alcohol and cigarette use. No causal factors were tested here, and it may be found that the same factors that predict increasing use of licit substances also predict multisubstance use. Nevertheless, an adolescent's relative increase in the frequency of cigarette smoking or alcohol use appears to be more prognostic of multisubstance use

than is the mere frequency/quantity, even when frequency/quantity is high. Efficient targeting of early intervention efforts would focus on alcohol and cigarette users, and efforts would concentrate on preventing further progression to heavier levels of use and the often accompanying patterns of multisubstance use. □

Determinants of Passive Smoking in Children in Edinburgh, Scotland

Martin J. Jarvis, MPhil, David P. Strachan, MRCP, and Colin Feyerabend, PhD

ABSTRACT

Objectives. Using saliva cotinine as a quantitative marker, we examined the contribution of factors other than parental smoking to children's passive exposure to tobacco smoke.

Methods. Saliva specimens from a random sample of 734 7-year-old schoolchildren in Edinburgh, Scotland, were analyzed for cotinine. Their parents completed a questionnaire covering smoking habits and conditions in the home.

Results. A number of independent predictors of cotinine were identified in addition to the main one of smoking by household members. These predictors included home ownership, social class, day of the week, season of the year, number of parents present, crowding in the home, the number of children in the household, and sex. Cotinine was higher in children from less advantaged backgrounds, during winter, on Mondays, in girls, and when fewer other children were present. The effects were similar between children from nonsmoking and smoking homes.

Conclusions. Questionnaire measures of parental smoking are insufficient to fully characterize young children's exposure to passive smoking. Because socioeconomic variables contribute to measured exposure, passive-smoking studies that treat class as a confounder and control for it may be overcontrolling. (*Am J Public Health.* 1992;82:1225–1229)

Introduction

Studies examining the effects of passive smoking on children's health have mostly used questionnaire measures of parental smoking habits as their indicator of exposure to environmental tobacco smoke. This approach has given rise to an impressively consistent body of findings implicating passive smoking as a cause of respiratory illness in babies and young children.[1] However, commentators have pointed to the imprecision of questionnaire-based methods in quantifying exposure,[2,3] and in recent years an increasing number of studies have incorporated biochemical markers, principally cotinine, as objective measures. As a major metabolite of nicotine, cotinine is a sensitive indicator of the absorption of smoke products.[4] Several groups[5–11] have found dose-response relationships between the extent of smoking by household members and salivary or plasma cotinine concentrations in children, and associations between cotinine and low birth weight,[12] middle ear effusion,[13] and impairment of lung function[14] have been reported.

Despite the acknowledged importance of smoking by parents in determining their children's exposure to passive smoking, detectable concentrations of cotinine are found in the majority of children from homes where there are no smokers. In a study of 7-year-old children attending primary schools in Edinburgh, Scotland,[14] we noted that three quarters of the children from nonsmoking households had detectable salivary cotinine, and 10% of this group were in the upper two fifths of the distribution of measured tobacco-smoke exposure. This suggested that factors other than smoking by household members may be significant influences on exposure for some children. We have conducted further analyses of the data from the Edinburgh study in an attempt to identify determinants of exposure in addition to that of smoking by household members.

Subjects and Methods

A sample of 30 primary schools in Edinburgh (one third of all Edinburgh primary schools) was chosen at random and the parents of all children in the third year (aged 6 1/2 to 7 1/2 in September 1986) were contacted by postal questionnaire (n = 1095). The questionnaire inquired about respiratory symptoms in the child and conditions in the home. Usable replies were obtained from 1012 (92%), and written consent to further tests was obtained for 941 children (86% of the target sample). Twenty of these children left school before the survey began, and a further 20 were used in pilot studies. This left 901 children, of whom 892 participated in a clinical examination at school. Children were examined from January to June 1987 by Strachan. Measures taken included spirometry and a tympanogram. Full details of these procedures have been reported elsewhere.[13,14,15]

[a]None detected (< 0.1 ng/ml).

Children were asked to collect saliva in the mouth and to spit into a clean plastic container. A satisfactory specimen was obtained from 779 children (87% of those examined). The saliva samples were frozen within 8 hours of collection for later cotinine assay by gas-liquid chromatography, using a method with a detection limit of 0.1 ng/ml.[16]

On the questionnaire sent to parents, the question used to investigate smoking in the household was "How many people in your household smoke cigarettes?" Responses were coded as none, one, or two or more. Smoking by mothers, fathers, and others in the household was not separately ascertained. Social class was coded according to the British Registrar General's classification of occupations. Home ownership was categorized as rented (mainly low-income housing owned by the city) or owner-occupied. One-parent homes were defined as those where only one adult was reported as usually living in the household. An index of crowding was calculated by dividing the number of people in the household by the number of rooms (other than kitchen, bathroom, and toilets). Three levels were defined: low (less than one person per room); medium (one person); and high (more than one person). Day of the week when the examination was conducted was divided into Monday vs Tuesday through Friday. It was anticipated that this would permit identification of any differences in exposure between weekends and other times of the week. Season of the year of the examination was divided into winter (January to March) and spring (April to June).

Because the distribution of saliva cotinine values was highly skewed, a logarithmic transformation was applied to the values prior to statistical analysis, undetectable concentrations being assigned a value of 0.05 before transformation. We used multiple regression analyses to assess the independent association of predictor variables with measured saliva cotinine. Analyses of covariance were used to estimate the geometric mean cotinine concentration for each level of each predictor variable before and after adjusting for all other significant predictors.

Results

From a total of 779 children with cotinine data available, 6 had concentrations over 14.3 ng/ml, which has been suggested as a cut-off point to define active smoking[17] (values were 16.5, 17.1, 18.7, 21.0, 25.5, and 36.1 ng/ml). All of these children came from homes with at least one smoker, and it is possible that their high values were due entirely to breathing in other people's smoke. But since smoking is not unknown even in children as young as 7, and to avoid possible bias in assessing passive smoking effects, they were excluded from the analysis. A further 39 children had missing data on one or more variables of interest. This left a final sample of 734 children, of whom 16% had 2 or more smokers at home, 30% one smoker, and 53% no smokers. The equivalent percentages in the original sample of 1012 children for whom questionnaires were completed were 16, 31, and 53, indicating that the final sample was fully representative of the target population. Table 1, which gives percentiles of the distribution of saliva cotinine by household smoking, shows that cotinine concentrations were strongly influenced by the number of smokers living in the home. The median concentration was 0.2 ng/ml among children from nonsmoking homes, 1.80 ng/ml where one smoker was present, and 4.40 ng/ml where there were two or more smokers. The correlation between log cotinine and the number of smokers in the home was 0.71, indicating that this variable accounted for 51 percent of the variance in measured cotinine values.

Our approach to modeling saliva cotinine concentrations was to enter predictors with more than two levels as trend variables. In the case of household smoking, a slightly improved fit could be obtained by including separate dummy variables for one-smoker and two-smoker households. However, for simplicity of presentation, this variable was also treated as a linear trend. Table 2 gives the results of the multiple regression analysis. It shows that there were a number of other variables, in addition to household smoking, that reliably predicted cotinine concentrations. The indicators of socio-economic status—home ownership and social class—together accounted for a further 11% of the variance in cotinine. There was an inverse linear relationship between social class and cotinine, and, independently of this, children living in rented accommodations had higher concentrations than those from owner-occupied homes. Figure 1 shows that these effects were found among children from nonsmoking as well as smoking households. Children from one-parent households had concentrations considerably higher than other children's, and this effect was present whether or not the parent was a smoker. Both day-of-the-week and season-of-the-year effects were evident, concentrations being higher in winter than in spring, and in children examined on a Monday than on other days. Not unexpectedly, crowding in the home was associated with higher cotinine concentrations, but there was also a linear inverse relationship with the number of children living in the home. Finally, girls had higher measured exposure than boys.

Although statistically significant, the magnitude of these various effects was

generally small. For example, the difference in adjusted means between boys and girls was 0.14 ng/ml, similar to the day-of-the-week effect. However, there was a difference of nearly 0.5 ng/ml between children from professional homes and those with unskilled parents, and the single-parent effect was close to 1.0 ng/ml. When all predictors were entered, the percentage of variance in saliva cotinine accounted for was 68%. Variables that were examined but did not predict cotinine included the type of fuel used for cooking and heating, the presence of dampness in the home, and whether or not bedroom windows were reported as usually left open at night.

We examined the data for interaction effects between the main predictor variables, but none were identified. Because there were a number of predictors of cotinine besides the major one of the presence of smokers in the household, we analyzed how much of the limited variance in the group of children from nonsmoking homes (n = 392) these predictors could account for (Table 3). All predictors identified in the main analysis continued to show significant associations with cotinine. Overall they accounted for 33 percent of the observed variance. The direction and magnitude of these effects were generally similar to those found in smoking households (analysis not presented), confirming the lack of any significant interaction between these variables and parental smoking.

Note. Variables listed in order of entry to a stepwise analysis. Regression coefficients and significance levels derived from a forced entry analysis in which all predictors were entered simultaneously. R^2 = .69; adjusted R^2 = .68; multiple r = .83.
[a]The regression coefficients shown have been exponentiated to represent the multiplicative effect on cotinine levels associated with a unit increase in the predictor variable.
[b]Coded according to the British Registrar General's classification of occupations.

Discussion

Our findings confirm the importance of smoking in the home in determining the extent to which young children breathe in other people's smoke, but they also show that a range of other factors also influence exposure. Smoking by adults living in the home accounted for 51 percent of the observed variance in saliva cotinine concentrations, while an additional 17 percent could be attributed to socioeconomic status, demographic factors, time at which the examination was conducted, and the extent of crowding in the home. The results—particularly for nonsmoking households—indicate that parental smoking habits as ascertained by questionnaire responses are inadequate to fully determine young children's exposure to environmental tobacco smoke.

Socioeconomic factors influenced the extent of exposure in two ways. First there was an association with the presence of smokers in the home (75% of children from blue collar, rented homes had one or more smokers at home compared with 29% of children from white collar, owner-occupied homes). But both social class and home ownership had further effects on measured exposure after controlling for the presence of smokers living in the home. Higher cotinine concentrations were associated with living in rented accommodations, and, in addition, concentrations showed an inverse linear relationship with social class as indexed by occupation of the head of household. This indicates that children from more deprived homes suffer additional exposure to passive smoking, possibly either through smoking by visitors to the home or by moving through a more smoke-polluted environment outside the home (stairwells, transport, shops, etc.).

Interpretation of the crowding effect observed would seem straightforward, implying simply that it is harder to avoid tobacco smoke the greater the number of people sharing the same living space. But the inverse association between number of children in the household and measured exposure was unexpected and harder to

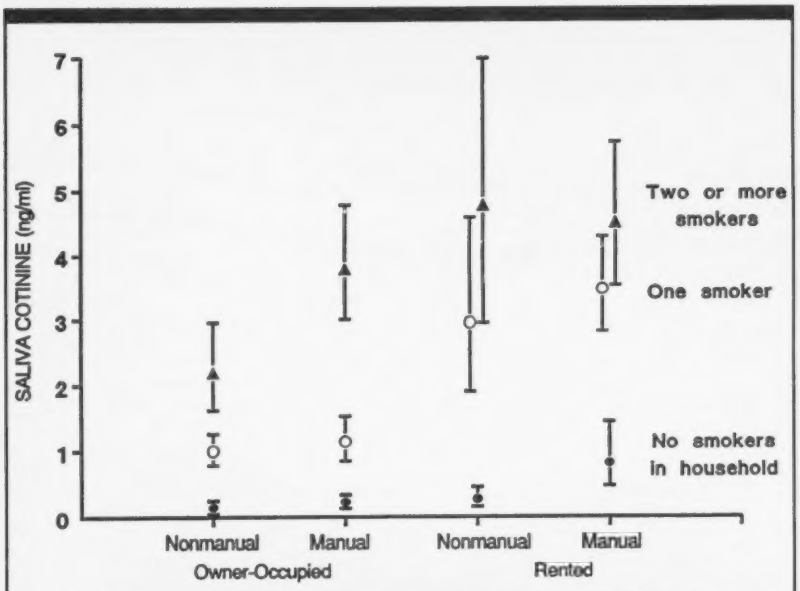

FIGURE 1—Geometric mean saliva cotinine concentrations (± 95% CI) by home ownership and social class among children from smoking and nonsmoking households.

[a]The regression coefficients shown have been exponentiated to represent the multiplicative effect on cotinine levels associated with a unit increase in the predictor variable.

account for. One explanation might be that each child functions as a kind of biological vacuum cleaner, so that the more children there are, the less smoke each can collect by breathing in. However, we found no similar effect for the number of adults in the household. More plausible is the notion that the more children there are, the more they will play with each other away from adults, and the more competition there will be for space close to parents.

Seasonal variation in saliva cotinine levels is likely to reflect better ventilation of the home in warmer, spring weather than in the winter. The Monday effect may reflect the fact that during the week the child spends a considerable portion of the time in the nonsmoking environment of the school, while during the weekend the home environment would predominate. Since cotinine has a half life in saliva of about 16 hours,[18] exposure during the weekend would have a considerable bearing on levels measured on a Monday. The existence of these effects of time of sampling suggests that studies will need to specify such factors carefully if their results are to be comparable.

The associations we have documented are clear-cut, but could they be due to factors other than passive smoking? Nicotine is not entirely specific to tobacco, being found for example in small amounts in peppers, aubergines, and potato skins.[19] Although it has been suggested that dietary factors may substantially influence cotinine levels,[20] a number of considerations strongly argue against this interpretation. It has been pointed out that people would have to eat huge amounts of these vegetables to have any measurable effect on their cotinine levels.[21] The putative dietary factors would also have to show exactly the same distribution in the population as parental smoking habits. Aside from this, the dietary hypothesis either offers no obvious explanation for observed associations (e.g., crowding, seasonal effects), or the direction of any postulated effect would be the opposite to that observed. Families in rented homes or with unskilled occupations would be expected to eat fewer vegetables, even though their cotinine concentrations are higher.

There was very considerable restriction on the range of cotinine values observed in children from nonsmoking homes. The median was 0.2 ng/ml and the 90th percentile 1.20 ng/ml. Despite this restriction, predictors emerged that were similar to those among smoking households, indicating that the reason measurable cotinine concentrations are found in children from nonsmoking homes is that in many cases they are still subject to a range of determinants of passive smoking. It would appear that the only practical way to determine their exposure is by means of a sensitive marker of actual smoke uptake.

Epidemiological investigations of passive smoking have treated variables such as social class and home ownership as potential confounders and have thus controlled for them in their statistical analysis of the relationship between exposure to passive smoking and disease endpoints. Our results indicate that in so doing they may be overcontrolling, because socioeconomic status and a number of other variables may each independently predict exposure to environmental tobacco smoke. Wherever possible, investigators should supplement or replace questionnaire data with quantitative measures of actual smoke uptake. □

Call for Abstracts for Epidemiology Late-Breaker Sessions

Exchange Session

The Epidemiology Section will sponsor a "late-breaker" Epidemiology exchange on Wednesday, November 11, 1992, during APHA's 1992 annual meeting in Washington, DC. The exchange will provide a forum for presentation of investigations or methods that have been conceived, conducted, and/or concluded so recently that members could not meet the deadline for abstract submission to other Epidemiology sessions. Abstracts should report on work conducted during the last 6–12 months.

Abstracts of fewer than 200 words (any format) and a stamped, self-addressed return envelope should be submitted to Polly A. Marchbanks, PhD, Chief, EIS Program, Epidemiology Program Office, Mailstop C08, Centers for Disease Control, Atlanta, GA 30333; (404) 639-3588.

Abstracts must be *received* by September 28, 1992. Decisions will be made by October 5, 1992.

Poster Session

The Epidemiology Section will again be sponsoring a late-breaker poster session at the annual meeting. The session will take place on Wednesday, November 11, 1992. Work completed in 1992 is eligible for consideration. Submit an abstract of fewer than 200 words (any format) and a *return envelope* to Cathey Falvo, MD, MPH, Graduate School of Health Science, Munger Pavilion, New York Medical College, Valhalla, NY 10595; tel. (914) 993-4323.

Abstracts must be *received* by October 2, 1992. Decisions will be mailed October 5, 1992. Students and recent graduates are particularly encouraged to submit abstracts.

Cigarette Smoking and Occupational Status: 1977 to 1990

Lirio S. Covey, PhD, Edith A. Zang, PhD, and Ernst L. Wynder, MD

ABSTRACT

Objectives. In this study we examined the relationship between occupational status and smoking habits in men and women during the period from 1977 to 1990.

Methods. Cigarette smoking and occupational history were obtained from 8045 men and women who served as controls for a hospital-based study of tobacco-related diseases.

Results. There was an association between increasing occupational status and tobacco exposure in men, but not in women. The quit rate increased over time in all sex-occupational groups except for male laborers, whose quit rate remained constant. Nicotine-dependent smokers are likely to find it difficult to quit. Male nicotine-dependent smokers were consistently found in greater numbers among blue collar workers throughout the study period. Initially, female nicotine-dependent smokers were more often found among blue collar workers, but in recent years became more frequent among white collar workers.

Conclusion. These trends provide clues to the future epidemiological distribution of lung cancer and other tobacco-related diseases. An understanding of gender differences in the occupational profile of cigarette smokers can provide guidelines for effective antismoking interventions. (*Am J Public Health.* 1992;82: 1230–1234)

Introduction

Ten years ago, we reported observations from a hospital-based epidemiological study that indicated a strong relationship between occupational status and smoking behavior in men.[1] Men in white-collar occupations, particularly those in professional-level jobs, were less likely to have ever smoked. Among individuals who did smoke, men in white-collar occupations were more likely to have quit, and among those who continued to smoke, white-collar workers were more likely to be smoking cigarette brands with lower tar and nicotine yields. The higher prevalence of cigarette smoking in male blue-collar workers than in male white-collar workers was also observed in representative samples of the US population.[2]

During the past decade, we have continued to obtain detailed smoking and occupational information from the same epidemiologic study that provided the database for our earlier study.[1] These data enabled us to perform an updated examination of the relationship between occupational status and smoking habits in both men and women, and to record the changes in smoking behavior by occupational category over the years 1976 to 1990. Additionally, using criteria suggested by the work of Fagerstrom,[3] we estimated the prevalence of "nicotine-dependent smokers" in each occupational group, by sex.

Methods

The data used in this analysis were collected as part of a large ongoing study of tobacco-related diseases that has been described elsewhere.[4] We included 8042 subjects (4985 male and 3057 female controls in the database) who were recruited between the years 1977 and 1990 from hospitals located in the New York, Long Island, and Chicago metropolitan areas in the United States and who did not have a history of tobacco-related diseases, such as cancers of the lung, oral cavity, larynx, esophagus, pancreas, kidney, or bladder; myocardial infarction, stroke, angina pectoris, or peripheral vascular disease; chronic bronchitis or emphysema. Among the admission diagnoses were malignancies (of the stomach, colon, prostate, and breast; leukemias; lymphomas; multiple myeloma; sarcomas), benign neoplasms, and acute or chronic conditions (e.g., cataracts, glaucoma, arthritis, fractures). Breast cancer in women (10%) and colorectal cancer in men (3%) were the most frequent diagnoses.

All data were collected by means of a detailed, standardized questionnaire filled out by trained interviewers; the questionnaire included information on demographic factors, smoking history, and occupation. Non-Whites and individuals younger than 40 years each constituted only approximately 5% of the population in the database, and they were excluded from the analyses.

Occupational Classification

Occupational classification was elicited by the question, "What has been your

[a]Labor, operative, service.

usual occupation?" Responses were coded according to the categories employed by the US Bureau of the Census: professionals, managers, sales and clerical workers, craftsworkers, laborers, operatives, and service workers.[5] In addition, we included a separate code for homemakers, to designate women who had not generally been employed outside the home. Because of the small numbers, laborers, operatives, and service workers were grouped together as laborers in the analyses of data for men. For women, we combined professionals and managers into a single category, and craftsworkers, laborers, operatives, and service workers were classified as blue-collar workers.

Measures of Smoking Behavior

"Ever smokers" were defined as those who had ever smoked cigarettes at least once a day for 1 year. "Current smokers" included those who either were smoking at the time of the interview or had stopped less than 12 months earlier. Persons who smoked pipes or cigars, either alone or in addition to cigarettes, were excluded from the analyses. Rates of ever smoking and current smoking were both calculated using the total sample size in each sex-specific occupational group as the denominator.

"Quitters" were defined as previous smokers who had not smoked during the previous year, and the proportion of quitters was calculated using the total number of ever smokers in each sex-specific occupational group as the denominator. Additionally, we calculated the proportions of smokers who smoked more than 30 cigarettes per day, of those who smoked cigarettes yielding more than 20 milligrams of tar, and of nicotine-dependent smokers, each time using the total number of current smokers in each sex-specific occupational category as the denominator.

Drawing from the literature on the Fagerstrom Tolerance Questionnaire,[2] we defined nicotine-dependent smokers as current smokers who smoked more than 25 cigarettes per day and who lit up in the morning within 30 minutes of awakening. It has been shown that these two behaviors are both highly associated with biochemical measures of smoking—for example, cotinine and nicotine in the serum[6]—and are most characteristic of smokers who are unable to quit.[7]

Data Analysis

The percentages of individuals in each of the above smoking categories were calculated by occupation and sex.

TABLE 2—Specific Smoking Behaviors in Men, by Occupational Status, in Three Time Periods

	Time 1 (1977–1980) n = 1568	Time 2 (1981–1984) n = 1703	Time 3 (1985–1990) n = 1714	Difference Time 3 – Time 1

Laborer/operative	46.0	40.0	51.4	+5.4

Note. All figures are percentages.
[a]Based on ever smokers.
[b]Based on current smokers.

We examined temporal changes in smoking by dividing the data into three time intervals: 1977 to 1980, 1981 to 1984, and 1985 to 1990. Although the time intervals correspond with progressively expanded and modified versions of the survey instrument, none of the revisions involved the variables analyzed in this study.

The three geographic areas (Chicago, Long Island, and New York) that served as the sources for recruitment of our sample did not yield substantially different distributions by age, occupation, and smoking exposure. We therefore combined them in subsequent analyses.

Results

Demographic Characteristics

The characteristics of the study population are summarized in Table 1. In men, the age distribution was relatively consistent over time; more than 80% of the sample were older than 50 years of age, and roughly half were older than 60 years of age. The proportion of college-educated men in relation to those with only an elementary education increased slightly over time. The sample included more Catholics than men of other religions, and more than 80% of the men were married. By geographic location, New York hospitals accounted for about 50% of the sample. About half of the men held white-collar jobs.

The demographic distributions of the women in the study resembled those of the men for all three time periods, except that fewer women were college educated and women were more likely than men to be widowed. Also, there were fewer women than men in professional and managerial occupations, but more in the sales/clerical category. In line with nationwide trends, the proportion of homemakers decreased over time.

The Relationship Between Smoking Behavior and Occupation

Men (Table 2). In each of the time periods, professional men were less likely to have ever smoked than were those in other occupational groups, and all groups except craftsworkers showed an increase in ever smokers from time 1 to time 3. The largest change, which occurred between time 1 and time 2, was seen among sales/clerical workers and laborers.

Professionals consistently had the highest quit rates, and men in blue-collar occupations had the lowest quit rates. Over time, quit rates increased and the proportion of current smokers decreased in all occupational categories with the exception of laborers. Blue-collar workers were twice as likely as professionals to be current smokers.

A less consistent association was found between heavy smoking (≥30 cigarettes per day) and occupation. Professionals were least likely to be heavy smokers, but sales/clerical workers surpassed blue-collar workers in heavy smoking at times 2 and 3, and they were the only group that showed an increase in heavy smoking over time.

In all categories except sales/clerical workers and laborers, the proportion of smokers who smoked high-tar-yield cigarettes decreased over time. The proportion of such smokers was consistently lower among white-collar workers.

Nicotine dependence was least common among professionals, particularly in time 2, and most common among blue-collar workers. In contrast to the general decline in smoking exposure (except among laborers), the proportion of dependent smokers showed an overall increase over time.

A noteworthy finding is the reduction in smoke exposure among craftsworkers, the most highly skilled blue-collar group,

among whom the proportion of current smokers declined while the quit rate continued to increase.

Women (Table 3). Fewer women than men smoked, and their smoking behavior was less clearly associated with occupation. Homemakers did not consistently resemble members of any other occupational category in their smoking patterns.

In contrast to men, proportionately fewer women white-collar workers had ever smoked. Blue-collar workers and homemakers showed a notable increase in this category over time.

Women's patterns of quitting were similar to those of men: quit rates were generally highest among professionals and managers and lowest among women in blue-collar jobs. Although homemakers resembled blue-collar workers in their increasing frequency of ever smoking, the proportion of quitters among homemakers was similar to that among white-collar workers. Overall, quit rates increased steadily over time among women. In accord with the trends in quit rates, professional women and homemakers were less likely to be current smokers than were women in blue-collar jobs. As with men, the numbers of current smokers diminished over time.

No consistent trend in the frequency of heavy smokers by occupation was evident among women. There was a general decline in heavy smoking, but this decline did not occur among those in sales and clerical positions.

Fewer women than men smoked high-tar-yield cigarettes, and the proportion of such smokers declined over time in all occupations. Women in blue-collar jobs were more likely to smoke the high-tar-yield brands, but they also showed the largest decrease in this behavior over time.

There was no clear relationship between occupation and nicotine dependence among the women in the sample, except that the proportions of dependent smokers increased in the white-collar occupations but decreased among blue-collar workers and homemakers.

Discussion

Although our study population consisted of hospitalized patients, the information obtained on their smoking behavior and usual occupation referred to their activities prior to their diagnoses. It is unlikely that these variables would have been influenced by their illness. An additional possibility of bias would be due to key differences in the populations sampled at the three time periods. However, as shown in Table 1, the demographic characteristics were approximately the same except for the overall increase in the educational level of the latest sample, which reflects a nationwide trend.

The results can be summarized as follows:

1. The apparent strong association between occupation and cigarette smoking among men that we reported 10 years ago continues.

2. Smoking behavior is much less related to occupation among women than among men.

3. The proportion of smokers who are most likely to have difficulty when attempting to quit, that is, nicotine-dependent smokers, is lowest among men in professional and managerial occupations. In women, dependent smokers were more frequently found among blue-collar workers and homemakers during the first period of observation (1977 to 1980). Over time, however, the proportion of nicotine-dependent smokers decreased among blue-collar workers and increased among women in white-collar occupations.

Among men, higher status occupations were generally associated with lesser smoking exposure as estimated by quit rate, current smoking prevalence, average tar yield per cigarette, and nicotine dependence. In contrast, although women in higher level occupations were more likely to have ever smoked, they were also more likely to have quit and to smoke lower-tar-yield brands than were those em-

ployed in lower level occupations. Homemakers, undoubtedly a heterogeneous group with regard to sociodemographic status, showed an irregular pattern in their smoking behavior as well as in changes over time; in some ways they resembled professional women and in others they resembled blue-collar workers.

Our results also indicate that women included fewer ever smokers than men, but that women had somewhat lower quit rates. Consequently, the proportions of current smokers were not much lower among women than among men, although women smoked fewer cigarettes per day, were less likely to smoke high-tar-yield brands, and were less likely to be dependent smokers. In a related paper, it has been shown that the women in this sample began to smoke later in life than did men and that this delayed onset of smoking was subsequently associated with a lower number of cigarettes smoked per day.[8] These findings suggest that although the incidence of tobacco-related diseases may continue to rise among women, as long as present smoking patterns prevail it will not reach the peak levels recorded for men.

The higher prevalence of tobacco use among men in blue-collar jobs is significant in light of the fact that these occupational groups are also more likely to be exposed to other hazardous substances through their work. Although broad estimates of lung cancer risk attributable to occupations range from 4% to 36%, with a mean of 13%, the estimated proportion of risk attributable to cigarette smoking is far greater, about 85%.[9] Consequently, increased efforts at reducing smoking exposure would contribute substantially to the overall reduction in the risk of lung cancer and other diseases related to both smoking and occupational exposures.

With the exception of male laborers, the proportion of current smokers in all occupations and in both sexes decreased over time, accompanied by a concurrent increase among current smokers in the frequency of nicotine dependence. This increasing proportion of individuals who are unable to quit points up the continuing need for efficacious smoking cessation intervention programs, particularly those targeted to reach the hard-core, nicotine-dependent smoker.

The difference by gender in the occupational profile of dependent smokers, who are predominantly blue-collar workers among men but predominantly white-collar workers among women, is intriguing. An understanding of the apparent interaction between gender and occupational status with regard to dependent smoking may lead to more efficacious smoking prevention and smoking cessation programs in the workplace. □

Predictors of Smoking Relapse after Noncardiac Surgery

ABSTRACT

Objectives. We studied 235 smokers who were admitted for major noncardiac surgery and who survived hospitalization to determine the frequency and predictors of smoking relapse 1 year after hospitalization.

Methods. We analyzed data collected prospectively from the Study of Perioperative Ischemia. We determined smoking status by self-report.

Results. At 12 months posthospitalization, 142 (76%) of the 186 surviving patients had resumed smoking. Significant independent predictors of relapse at 12 months were a history of alcohol abuse and a history of heavy cigarette smoking ($P < 0.01$ and $P < 0.05$, respectively).

Conclusions. Since smokers commonly undergo surgery, the perioperative period provides a valuable window of opportunity for smoking cessation interventions designed to decrease the high rate of smoking relapse after surgery. (*Am J Public Health.* 1992;82:1235–1237)

Joel A. Simon, MD, MPH, Warren S. Browner, MD, MPH, and Dennis T. Mangano, PhD, MD, for the Study of Perioperative Ischemia (SPI) Research Group

Introduction

About one in three adult men and one in four adult women in the United States continue to smoke despite the current ongoing public health efforts to encourage cessation.[1] As many as 90% of regular smokers would like to quit.[2] Because smoking represents the single most important preventable cause of loss of life in the United States, designing and implementing successful smoking cessation interventions is of obvious public health importance.[3] More than 25 million surgeries are performed each year in the United States,[4] providing a captive audience of smokers who usually must quit smoking, at least temporarily during the perioperative period.

The Study of Perioperative Ischemia (SPI) enrolled men with coronary disease or at high risk for it, who were undergoing elective noncardiac surgery.[5] Approximately half of these men were smokers. Since all smoking subjects were abstinent during the postoperative period, all were de facto quitters. To determine the epidemiology of smoking relapse among these men, our study followed these men prospectively and ascertained their quit rates at 12 months.

Methods

Subjects

The full details of the SPI have been described elsewhere.[5] The cohort consisted of 474 men at the San Francisco Veterans Affairs Medical Center who were scheduled for elective noncardiac surgery requiring general anesthesia and were enrolled consecutively between January 1987 and September 1989. Of these, 241 (51%) were self-reported smokers at the time of enrollment. Excluded from the analysis were 6 smokers who died during the initial hospitalization, 41 who died during the subsequent year, and 8 who were lost to follow-up. This left 186 subjects available for analysis at 12 months.

Measurements

Age, race, and marital status were ascertained after admission. Any history of coronary artery disease (CAD), congestive heart failure, valvular heart disease, peripheral vascular disease, cerebrovascular disease, treated hypertension, diabetes mellitus, or recent surgery was recorded. Patients were questioned regarding the use of bronchodilators, which this study used as a surrogate for the diagnosis of obstructive airway disease.

The current number of packs smoked per day and the number of years of smoking at this level were recorded on admission. Pack-year history of smoking was then estimated. Patients were also asked if they had a history of alcohol abuse, but there was no attempt to quantify level of alcohol use.

Smokers undergoing major vascular and intrathoracic surgery were considered

TABLE 1—Characteristics of the Study Subjects

	Subjects (n = 186)	
	No.	%
White	143	77
Black	28	15
Married	33	18
Coronary artery disease	80	43
Congestive heart failure	20	11
Peripheral vascular disease	93	50
Cerebrovascular disease	40	22
Diabetes mellitus	29	16
Alcohol abuse	102	55
Hypertension	91	49
Bronchodilator use	14	8
Type of surgery: Major vascular/intrathoracic	86	46
In-hospital cardiac event	12	7

Note. Subject characteristics calculated by mean ± SD included: age (y), 65 ± 8.7; current tobacco use (packs per day), 1.1 ± .66; pack-year history (n = 185), 40.8 ± 12.1; body mass index (kg/m^2; n = 177), 24.7 ± 4.2; and postoperative days, 15.4 ± 15.3.

together and compared with smokers undergoing all other operative procedures. Because major vascular and intrathoracic surgeries are often performed for diseases directly related to tobacco use, we believed that these smokers might be more likely to remain quitters postoperatively than those undergoing other surgical procedures. The number of postoperative days in the hospital was used to estimate length of hospital stay and initial tobacco abstinence.

Twelve-month postoperative follow-up of patients was performed by direct interview and included self-reported smoking status.

Statistical Analysis

Logistic regression analyses were performed with SAS Proc Logist.[6] Variables that did not meet the .10 significance level in the univariate models were not entered into the multivariate model. Odds ratios (OR) with 95% confidence intervals (CI) were calculated. Two-tailed t tests and Mann-Whitney U tests were done to compare continuous data, and χ^2 tests were performed for the analysis of categorical data.

Results

Our cohort was predominantly unmarried and White (Table 1). Alcohol abuse and peripheral vascular disease were common. Half of our patients were taking antihypertensive medications. The study subjects were, on average, moderate smokers at the time of entry, with 40 pack-years of tobacco use.

At 12 months posthospitalization, the rate of relapse was 76%. Smokers with a history of alcohol abuse were more likely than non-alcohol abusers to resume smoking (84% vs 67%, $P < .01$). Other significant univariate predictors of relapse at 12 months included CAD, pack-year history of smoking, and duration of hospitalization. Among CAD patients, 70% relapsed as compared with 81% among non-CAD patients ($P < .10$). Smokers with hospital stays of 2 or more weeks were less likely to relapse than smokers with shorter stays (66% vs 81%, $P < .05$), and relapsers had on average 5 fewer days of hospitalization ($P < .05$). Smokers with 50 or more pack-years of smoking had a relapse rate of 87% compared with 73% for the 30- to 49-pack-year smokers and 64% for smokers with under 30 pack-years ($P < .05$).

Multivariate analysis disclosed that only pack-year history of smoking and history of alcohol abuse were statistically significant independent predictors of relapse at 12 months (Table 2). Using the logistic coefficients to estimate the risk of relapse, a 40 pack-year smoker with a history of alcohol abuse had a 94% relapse probability compared with a 71% probability in a 20 pack-year smoker without a history of alcohol abuse.

None of the demographic variables (race, age, marital status) predicted relapse at 1 year, nor did current tobacco use measured in packs smoked per day. With the exception of the presence of CAD, no medical condition was associated with relapse.

Discussion

All the smokers enrolled in our study had the opportunity to turn an elective surgical procedure into a springboard for permanent tobacco cessation. Regulations at the San Francisco Veterans Affairs Medical Center proscribe smoking within the hospital; this information is conveyed to all patients at the time of hospitalization. While it is not uncommon for ambulatory patients to leave the hospital to smoke, it is not possible for patients to smoke on the day of their surgery and for several days after when confined to bed. Therefore, all SPI smokers quit using tobacco, if only for a brief period. Nonetheless, 76% of smokers had relapsed within a year. Relapse rates similar to ours have also been observed among patients hospitalized in coronary care units.[7]

The 1-year quit rate among SPI smokers, who did not have the benefit of an in-hospital smoking cessation intervention, was similar to the long-term quit rates associated with many outpatient stop smoking programs.[8,9] Analysis of the first National Health and Nutrition Examination Survey demonstrated an increase in the quit rate among smokers who had been hospitalized in the previous year.[10] Higher quit rates, up to 45%, have also been seen among smokers hospitalized with acute myocardial infarction.[11] Furthermore, our study demonstrates that the longer the hospitalization, probably reflecting poorer health status, the greater the likelihood of quitting.

Our study suggests that a history of addictive behavior, including long-term heavy tobacco use and alcohol abuse, may generally be predictive of smoking relapse. Other investigators have found that the measure "cigarettes smoked daily" does not predict those more likely to quit or less likely to relapse.[9,12] Pack-years of smoking, on the other hand, combines both duration with intensity of use, producing a measure of lifelong tobacco use that was clearly a better predictor of smoking relapse in our cohort than current tobacco use. Our patients with a history of alcohol abuse were also more likely to resume tobacco use. Alcohol is known to act as a relapse trigger along with other factors, such as stress, interpersonal conflict, and the presence of other smokers.[3]

There are a number of limitations to our study. First, our evaluation of predictors of smoking relapse was limited by the focus of the study—perioperative ischemia. We were therefore unable to assess the role of other potential correlates of smoking relapse, such as depression and education level. Thus, smoking cessation and relapse prevention programs for surgical patients will need to be based on a broader assessment of smoking relapse risk factors than can be provided from our study alone. Second, the SPI cohort was limited to men obtaining their surgical care at a Veterans Affairs hospital who had or were at high risk for CAD. Our results may therefore not be generalizable to younger, healthier patient populations with better social support systems and a lower risk of serious disease. Third, the pack-year history of smoking may have been underestimated if smokers reported cigarette consumption that was reduced prior to hospitalization. Fourth, all re-

ported quit rates were based on self-report by the study subjects. The actual relapse rate among the cohort is therefore likely to be somewhat greater than the 76% reported, particularly if the eight subjects lost to follow-up are also classified as relapsers. However, since smokers were enrolled in a study of the predictors of perioperative ischemia and not of smoking cessation, there was no incentive to overreport smoking cessation on follow-up. While nicotine intake is best assessed biochemically, self-report has been found to be a valid method for assessing smoking prevalence in observational studies.[3] Finally, because smoking relapse was common among our cohort, the ORs for pack-year history of smoking and history of alcohol abuse should not be interpreted as relative risks. The OR, a good approximation of the relative risk when an outcome is rare (generally less than 10%), overestimates the relative risk in our study because smoking relapse was so common (76%). The ORs nevertheless do reflect the importance of the association between the predictors in our study and smoking relapse.

The potential for achieving high long-term quit rates is demonstrated by the 71% quit rate achieved at 1 year among survivors of acute myocardial infarction who had the benefit of an in-hospital smoking cessation program.[11] This was a nurse-managed program using the principles of social learning theory and including outpatient follow-up. Similar programs focusing on smokers hospitalized for surgery—perhaps with special emphasis directed toward those most at risk for relapse, such as heavy long-term tobacco and alcohol users—could contribute to the continuing secular decline in tobacco use in the United States. Multimodality interventions that include self-help literature, audiovisual aids, nicotine gum, and counseling may prove the most effective. Well-designed randomized smoking cessation intervention trials for hospitalized patients are needed to answer this question. □

TABLE 2—Variables Associated with Smoking Relapse at 12 Months[a]

	OR (95% CI)[b]	P value
Univariate models		
History of alcohol abuse	2.69 (1.33, 5.40)	.006
Pack-year history (per 10 pack-years)	1.39 (1.05, 1.84)	.02
Postoperative days (per 7 days)	0.86 (0.75, 1.00)	.04
Coronary artery disease	0.54 (0.27, 1.07)	.08
	Adjusted OR (95% CI)[b]	**P Value**
Multivariate model		
History of alcohol abuse	3.07 (1.42, 6.66)	.005
Pack-year history (per 10 pack-years)	1.47 (1.09, 1.98)	.01
Postoperative days (per 7 days)	0.88 (0.75, 1.02)	.10
Coronary artery disease	0.49 (0.23, 1.03)	.06
Type of surgery[c]	0.50 (0.23, 1.10)	.09

[a]No other variables were significant at the $P < .10$ level.
[b]OR = odds ratio; CI = confidence interval. Because the risk of relapse was high, the ORs should not be interpreted as relative risks (see discussion).
[c]Major vascular and intrathoracic versus all other.

Smoking Cessation in Women Concerned about Weight

Phyllis L. Pirie, PhD, Colleen M. McBride, PhD, Wendy Hellerstedt, MPH, Robert W. Jeffery, PhD, Dorothy Hatsukami, PhD, Sharon Allen, MD, and Harry Lando, PhD

ABSTRACT

Background. **Weight gain after smoking cessation is often cited by women smokers as a primary reason for not attempting to quit smoking or for relapsing after a cessation attempt.**

Methods. **A randomized trial of 417 women smokers was conducted to test the addition of two weight control strategies to a smoking cessation program. Participants received the standard smoking cessation program, the program plus nicotine gum, the program plus behavioral weight control, or the program plus both nicotine gum and behavioral weight control. Weight and smoking status were measured at the end of treatment and at 6 and 12 months posttreatment.**

Results. **Smoking cessation rates were highest in the group receiving the smoking cessation program plus nicotine gum. Weight gain did not vary by treatment condition, so its effect on relapse could not be examined by group. There was no significant relationship between weight gained and relapse in individuals.**

Conclusions. **The added behavioral weight control program was attractive to the participants and did not reduce smoking cessation rates. However, it did not produce the expected effect on weight, thereby restricting our ability to examine the effect of weight control on smoking cessation and relapse. (*Am J Public Health.* 1992;82:1238–1243)**

Introduction

Men and women smokers in the United States are generally similar in their intentions to quit and their quit attempts,[1,2] and they are interested in similar types of cessation programs.[1] A major exception to this similarity is that women report substantially more concern about weight gain upon quitting[2] and are more likely than men to report using smoking as a weight control strategy.[3] Although it has been difficult to demonstrate that weight gain is a precipitant of relapse,[4] concern about weight gain may act as a barrier to quit attempts.

The research reported here is an investigation of treatments that incorporated weight control strategies into a well-tested smoking cessation program to create a program that is more acceptable and more attractive to weight-concerned women. The tested weight control strategies were a behavioral weight control program and nicotine polacrilex chewing gum. Nicotine gum, in addition to its demonstrated ability to enhance smoking cessation, has been reported to minimize weight gain among quitters in some studies[5–8] though not in others.[4,9]

Methods

Treatment Programs

The research design was a randomized factorial trial that tested nicotine gum and a behavioral weight control program alone and in combination; both were added components of the American Lung Association's Freedom from Smoking (FFS) clinic program. Participants were randomized to one of four groups: the FFS program; FFS plus the behavioral weight control program; FFS plus nicotine gum; or FFS plus both the behavioral weight control program and nicotine gum.

The FFS program, selected as one of the best widely available group programs,[10] is an 8-week program, with an orientation meeting plus seven treatment sessions. Meetings emphasize social support and the development of cognitive behavioral skills, such as anticipating and planning for high-risk situations, learning to cope, and preventing relapse. "Quit night" occurs in the fourth week of the program.

The behavioral weight control program was designed to help participants avoid weight gain and, should weight gain occur, to maintain a positive attitude about it. Weight control counseling accompanied each of the seven FFS sessions. Recommendations included decreasing caloric intake by 100 to 300 calories per day (depending on baseline cigarette consumption) and gradually increasing exercise to a goal of 1 hour of walking or its equivalent three times per week. Participants were given calorie counters and food diaries, which they were strongly encouraged to keep throughout the program.

This paper was submitted to the Journal August 21, 1991, and accepted with revisions April 7, 1992.

Editor's Note. See related editorial by Giovino et al. (p 1203) in this issue.

In the groups assigned to receive nicotine chewing gum, the gum (2-mg strength) was supplied free of charge during treatment and for 3 months after treatment ended, and participants were strongly encouraged to use it. Specific training was provided in how best to use the gum, and time was allotted in each group session for discussion about and reinforcement of its use. No specific amount of gum was prescribed although participants were urged to chew at least three pieces a day.

Facilitators were female ex-smokers who had been previously trained by the American Lung Association to be group leaders for the FFS program. For this research project, additional training was provided regarding the specific additional treatments. Each facilitator was trained to administer all four treatment conditions, and facilitators were crossed by condition. On-site observers in all groups monitored adherence to the specified treatment condition to ensure that material was not introduced inappropriately.

Characteristics and Recruitment of Participants

Participants were women aged 20 to 64 who wanted to quit smoking and to maintain their weight while quitting; women who expressed a desire to gain weight were excluded. Exclusions for medical reasons (because nicotine gum would be contraindicated) included those who were pregnant or planning a pregnancy; those who were nursing an infant; those with a history of gastric ulcer, substance abuse in the past 6 months, or cardiovascular disease including hypertension; those with temporal mandibular joint syndrome; and those undergoing active cancer treatment.

Recruitment and all program activities were conducted primarily in a Minneapolis suburban community. Subjects were recruited from two sources. First, a previous research study involving a population-based screening for cardiovascular risk factors generated a list of 2631 age-eligible women smokers. These women were contacted by telephone for assessment of initial eligibility and were invited to participate. Upon initial screening, 1785 of them were found to be eligible for the study and 264 were eventually randomized into it. Second, because of initial concern that the list of smokers from the screening project would not yield a sufficient sample, additional volunteer participants were solicited by word of mouth and by two small newspaper advertisements. These sources yielded 249 interested women, of whom 153 were eventually randomized. Recruitment overall was more successful than had been projected, and the goal of recruiting and randomizing 360 individuals was surpassed by 57 individuals, for a total of 417 randomized subjects.

To facilitate the continuous recruitment and enrollment of subjects without delay in the beginning of treatment, treatment was administered in four consecutive cycles, with each treatment condition represented within each cycle. Thus, there was a total of 16 treatment groups.

Data Collection Procedures

Interested women were invited to attend a baseline clinic, which included the completion of demographic questionnaires, smoking history, and weight history; weight measurement with a balance beam scale; the assessment of possible contraindications to nicotine gum; and the collection of biochemical measures of smoking status (i.e., expired air for measuring carbon monoxide and saliva for measuring thiocyanate and cotinine). Participants at the baseline clinic were given a detailed explanation of the study and asked to sign a consent form indicating their acceptance of study procedures. Those signing the consent form were then randomly assigned to a weeknight and site for class participation. At the orientation meeting, the treatment assignment was announced to the group. All participants who attended this orientation meeting were considered participants in the full study.

Compliance with treatment recommendations was assessed by session attendance, by self-report items regarding completion of smoking-related "assignments" (e.g., smoking records, reading materials, self-assessment exercises, etc.), and by self-report items in the appropriate groups regarding completion of food records and use of nicotine gum. Weight was measured with a balance beam scale at each group session. Expired air carbon monoxide was measured 1 week after the quit date and at the end of treatment (4 weeks after the quit date). Saliva was collected for biochemical (both thiocyanate and cotinine) validation at the end of treatment and was analyzed in the laboratory only for those individuals reporting themselves to be abstinent.

Follow-up data collection was conducted in a clinic, with assessments similar to those conducted at baseline at 6 and 12 months after the end of treatment. A detailed questionnaire asked about current smoking status and smoking since the last contact, relapse situations, and withdrawal symptoms. As was done at the end of treatment, saliva was analyzed only for those individuals reporting themselves to be abstinent.

Monetary Contingencies

Participants were asked to make a $100 deposit at the time of the baseline clinic; this deposit was to be completely refunded upon completion of the 12-month follow-up clinic, regardless of smoking status at that time. A small number of participants who could not pay $100 paid smaller amounts but never less than $40.

Definitions

Two definitions of abstinence were used in this study: continuous abstinence (no smoking at all since the program quit night) and point prevalence abstinence (no smoking in the past 7 days). Self-reported abstinence was verified by an expired air carbon monoxide reading of less than or equal to 10 ppm; if the value was higher than 10 in a self-reported nonsmoker, we accepted a cotinine value of less than or equal to 10 ng/mL (in the groups not receiving nicotine gum) or a thiocyanate value of less than 100 μmol/L (in the groups receiving nicotine gum) as evidence of nonsmoking. According to these criteria, only one individual was believed to be misreporting smoking status at follow-up, and that person was treated as a smoker in the analyses.

Analysis Methods

Differences between treatment groups were examined at baseline, at the end of treatment (session 7 of the FFS program), and at 6 and 12 months posttreatment using χ^2 analysis for categorical variables and general linear model procedures for continuous variables. The SAS package of statistical programs was used.[11] Preliminary analyses revealed no design effects for smoking—that is, no differences within treatments within cycles that could be considered specific to individual cycles. Hence, the analysis of treatment conditions was based on all randomized individuals without accounting for the cycle in which they participated.

Results

Baseline Comparisons

Table 1 shows selected baseline characteristics of participants randomized to each of the four treatment conditions. Participants in the four treatment conditions were statistically equivalent at baseline on all variables relevant to the treatment. Reported baseline smoking levels ranged from 4 to 105 cigarettes per day, with an average of 26.2 cigarettes. Although participants were concerned about weight, most did not appear to be obese; at baseline, they averaged 107% of the median recommended weight for height according to the recent (1983) life insurance industry tables.[12]

Process Measures

No incidents were recorded in which group leaders deviated from the assigned protocol for a given treatment group. Table 2 summarizes compliance data by treatment group. Meeting attendance was quite good, averaging 7.3 of 8 meetings. Self-reported compliance with treatment recommendations was more variable. Compliance with the smoking-related assignments differed across treatment groups in some sessions, with the best average for compliance reported in the group receiving both the behavioral weight control treatment and nicotine gum.

Follow-up Success

Data were collected in the follow-up clinics on 98.3% of participants at 6 months and on 98.1% of participants at 12 months. Those few participants who had moved out of the area were allowed to complete self-report assessments by telephone and mail, resulting in 100% participation in the follow-up assessments.

Weight Change Outcomes

Because weight gain was expected to be markedly different in smokers and nonsmokers and because length of abstinence was expected to be related to the amount of weight gained, weight change was analyzed at each follow-up point for the subgroup who remained continuously abstinent for the entire 12 months of follow-up (n = 88) and the subgroup who reported smoking continuously throughout the 12 months of follow-up (i.e., those who were smoking at each follow-up point) (n = 176). As expected, weight gain was pronounced in continuous abstainers, averaging 10.6 lb by the 12-month follow-up; it was very slight in the continuous smokers (1.6 lb by 12 months) (Table 3). Most of the weight gained was gained by the 6-month follow-up. Among those who were continuously abstinent, 70.5% gained at least 5 lb by the 12-month follow-up.

Although our treatment hypothesis was that abstinent individuals in groups receiving the behavioral weight control treatment or nicotine gum would demonstrate lower weight gains than individuals receiving the standard treatment, that was not the case (Table 4). Among the yearlong continuous abstainers, no significant differences in weight gain are seen between any of the treatment conditions at any follow-up point. During treatment, it appears that successful quitters in the treatment conditions that included the behavioral weight control treatment began to lose weight until quit night (session 3), after which their weights returned to and exceeded baseline levels (data not shown).

Among those abstinent at the end of treatment, weight gain was not found to be significantly different for those who were chewing gum versus those who were not, nor did it vary according to the amount of gum chewed. Similarly, at 6-month follow-up, weight gain was not found to be significantly different for those who were chewing gum versus those who were not.

Smoking Outcomes

Significant differences in abstinence among the treatment conditions are seen at each follow-up point (Table 5). The group receiving nicotine gum demonstrated the highest point prevalence and continuous abstinence rates at each follow-up point, whereas the group receiving just the basic smoking cessation program demonstrated the lowest smoking cessation rate at each follow-up point.

Session 5	...	...	...	...	...	...	108	29	20, 37	98	47	37, 57
Session 6	...	...	...	...	...	...	108	23	15, 31	98	32	22, 41

Note. FFS = Freedom from Smoking program; nicotine gum = nicotine gum condition; behavior = behavioral weight control condition.
[a]Acceptable levels of compliance are defined as follows: Attendance = present for at least seven sessions; compliance with smoking program assignments = self-report of at least "moderate" effort put into the assignment; compliance with nicotine gum recommendation = chewing at least three pieces per day; compliance with food records = self-report of keeping a record of "all" or "most" foods eaten. Those absent from a session are assumed to be below the acceptable level of compliance on measures taken at that session.

Given that we were unable to produce significant differences in weight gain across the treatment conditions, we are unable to analyze the effects of weight gain on smoking status at the group level. At the individual level, we found that, among successful quitters who had gained more than 5 lb by the end of treatment, the proportion who relapsed to smoking by the 6-month follow-up was 51.2% (95% CI = 36.3%, 66.1%), as compared with 39.9% (95% CI = 32.9%, 46.9%) in quitters who had gained 5 lb or less. Of those who were not smoking at the 6-month follow-up and who had gained more than 5 lb, the proportion who relapsed to smoking by the 12-month follow-up was 19.4% (95% CI = 11.8%, 27.0%). This compares with 13.2% (95% CI = 2.4%, 24.0%) relapsing among those who had gained less than 5 lb.

By 12-month follow-up	1.62	0.35, 2.89	10.60	8.84, 12.4

Discussion

Self-reports from smokers, which suggest that weight gain is a common cause of relapse to cigarette smoking, lead to the expectation that the individuals who gained more weight following smoking cessation would demonstrate higher levels of relapse. Our ability to test this hypothesis was compromised, however, by our lack of success in producing differential weight changes among the treatment groups in this study. This outcome was unexpected, given that behavioral treatments of the type used here have been used successfully in many weight loss programs, and nicotine gum has often been shown to reduce weight gain in quitters who chew it. Compliance data may supply part of the explanation. Although excellent compliance was recorded for meeting attendance and use of nicotine gum, self-reported compliance with other treatment recommendations (e.g., completion of smoking-related assignments and of food records) was not as good. Compliance with the behavioral weight control intervention apparently declined following quit night, indicating perhaps that complying with two behavioral interventions simultaneously was difficult for participants.

At the individual level, women who

[b]No smoking at all since the program quit night.

gained more weight were not significantly more likely to relapse to smoking than women who gained less weight. At least one study[4] has found that those who gained more weight by the 6-month follow-up were more (rather than less) likely to be abstinent at 12 months. The results of the two studies may be partly related to the stage at which weight gain is assessed. It may be that extremely weight conscious individuals tend to respond to small increments in weight by relapsing in the early period. Among those who have managed to remain abstinent by 6 months, however, weight may be less of an issue. Hence, weight gain may be unrelated to further relapse, as in our study, or it may even be a marker for those who are strongly motivated enough to continue abstinence, as in the Hall et al. study.[4]

It is also surprising that we did not observe differential weight gain in those chewing and not chewing nicotine gum. Although many studies report the weight control effects of nicotine gum, it is not clear from the literature how much gum is needed to produce such effects, nor how long the gum must be used to produce this result. We saw no enhanced weight control, not even in those chewing 10 pieces a day at the end of treatment or in those continuing to use gum at 6 months as compared with those not using it.

As expected, this study demonstrated that adding nicotine gum to a group-based program can produce outstanding validated cessation results at the 12-month follow-up. This has also been demonstrated in other studies.[13] However, the treatment group receiving both nicotine gum and the behavioral weight control program as adjuncts to the FFS program produced smoking cessation rates that were significantly lower by the 12-month follow-up than those for the group receiving just nicotine gum as an adjunct to the basic program. The hypothesis that the combination of several treatments resulted in "overload" on the part of the participants is attractive but unproven. For example, there is no evidence that individuals in the group receiving the combined intervention demonstrated poorer compliance with treatment recommendations than those in the nicotine gum group; in fact, the group receiving the combined intervention generally had the highest compliance rates.

It is clear, though, that even the combined treatments did not detract from the smoking cessation outcome of the program. On average, those receiving the weight control treatments did as well as or better than those receiving the standard FFS program, and all the treatment conditions did about as well as or better than comparable group treatments reported elsewhere.[14] Thus, it is clearly not the case that adding weight control components will reduce the smoking cessation that can be achieved by a high-quality group program.

An unexpected observation made in the course of implementing this program was the attractiveness of the program to potential participants; the program roster was easily filled and even overfilled by the final enrollment cycle. In our previous ex-

periences with Minnesota communities, recruitment had been much more difficult. For example, Schmid et al.[15] had recruited about 1.4% of smokers in two communities to home correspondence courses, and Lando et al.[16] report that several communitywide smoking cessation contests had attracted 3% to 5% of smokers in each community. In contrast, this project, with careful eligibility screening and a required monetary deposit, succeeded in randomizing 14.8% of an identified population of smokers. It appears that smokers perceive a need for programs that will address their legitimate concerns about gaining weight when they quit smoking. It is possible that some of the participants in this program may not have been willing to participate in other, more traditional smoking cessation treatments. For this reason if for no other, continued investigation of combined weight control and smoking cessation treatments is warranted. □

Acknowledgments

This research was supported by grant no. CA41647 from the National Cancer Institute; Phyllis L. Pirie was principal investigator.

The assistance of Ms. Penny Gottier of the American Lung Association, Hennepin County affiliate, is gratefully acknowledged. The authors also wish to acknowledge the efforts of Ms. Karen Virnig, who organized and supervised the initial telephone contacts and much of the follow-up data collection, and Ms. Gail Dolliff, who organized and supervised the baseline and follow-up clinics.

ASPO/Lamaze 1992 Childbirth Conference

From October 15 to 17, 1992, the American Society for Psychoprophylaxis in Obstetrics, Inc. (ASPO)/Lamaze will hold its annual conference at the Anaheim Hilton and Towers in Anaheim, Calif. The conference theme, "Childbirth: Choices and Challenges," reflects the diversity of issues and alternatives within the field of childbirth education. The highlights of the program will include dynamic keynote speakers, substantive educational sessions, dozens of exhibits, and special programs.

More than 600 childbirth educators, nurses, nurse-midwives, physicians, and consumers are expected to attend. Seminar topics will focus on the expanding roles, responsibilities, and technologies facing childbirth educators and parents today. Fifty-two professional development and educational sessions will be conducted by leading authorities in health care and Lamaze childbirth education. Optional programs include "Birth as a Cultural Mosaic," for both novice and expert educators, and "How to Establish a University ASPO/Lamaze Certification Program." The exhibit hall will feature more than 40 suppliers of products and services related to Lamaze childbirth education and perinatal health care.

For more information on the conference, contact ASPO/Lamaze at 1101 Connecticut Ave, NW, Suite 700, Washington, DC 20036; tel. (202) 857-1128.

How Women's Adopted Low-Fat Diets Affect Their Husbands

ABSTRACT

Objectives. One way of promoting a reduction in dietary fat intake is by changing the diet of family members. This study investigated the long-term effects of a low-fat dietary intervention on husbands of women who participated in the Women's Health Trial (WHT).

Methods. An average of 12 months after the end of the WHT, a randomly selected sample of participants' husbands was sent dietary and health questionnaires as part of a follow-up study of the maintenance of the low-fat diet among WHT participants.

Results. We found an absolute difference in fat intake between groups of 4 percentage points (32.9% energy from fat among intervention husbands [n = 188] vs 36.9% among control husbands [n = 180]). The wife's attitude and fat intake were among the most important predictors of her husband's fat intake, indicating that the effect of the WHT intervention on the husbands of participants was more likely due to their acceptance of lower-fat foods being served at home than to overt actions by the men.

Conclusions. Our results suggest that a dietary intervention aimed at women can have an effect on their husbands and may be a cost-effective approach to healthy dietary change for both women and men. (*Am J Public Health.* 1992;82:1244–1250)

Introduction

A diet high in fat has been implicated in both animal and epidemiologic studies as an important etiologic factor in a variety of diseases, including cardiovascular diseases and cancers of the colon, breast, and prostate.[1] *The Surgeon General's Report on Nutrition and Health* identified reduction of dietary fat consumption as the primary dietary priority for the general public as well as for special high-risk populations.[2] Recent research has focused on community-level interventions[3] and health promotion at worksites[4,5] and in schools[6,7] as potential effective and cost-efficient means of changing dietary and other health behaviors. In addition, the family has been identified as the primary unit in illness and health-related behaviors[8,9] and there is increased interest in effective ways to promote positive health habits within families.[6,10]

While there is evidence to suggest that eating patterns are shared within families,[11,12] there is little empirical research on the transfer of new dietary habits from one family member to another. Research has typically focused on family-based interventions[10,13,14] and on the effect of the family or spouse as a social support system on an individual's ability to modify dietary intake or other health behavior.[15] Only a few studies have addressed the impact of an intervention given to one individual on behavior change among his or her family members.[6,16–18] Although they suggest an important avenue of behavior change, these studies were small,[17] participants were self-selected or there was no control group,[6,18] or the research did not address the mechanism for the transfer of dietary patterns between spouses.[16] Thus, the purpose of this study was to address these shortcomings by studying the diffusion of dietary habits from women in the Women's Health Trial (WHT) to their husbands.

The WHT was designed to assess the feasibility of a large multicentered, randomized trial of a low-fat dietary intervention among women at moderately increased risk for breast cancer. Nutrient estimates based on a self-administered food frequency questionnaire indicated that intervention women had reduced the fat in their diet from 40% of energy intake at baseline to 26% at the end of the trial, compared with 39% and 38%, respectively, among control group women.[19] A follow-up study was conducted an average of 12 months after the end of the WHT to investigate maintenance of the low-fat dietary intervention and to determine predictors of this maintenance.[19–21] The intervention women had successfully maintained the low-fat diet at follow-up, with an (absolute) increase in dietary fat intake of only 1.4 percentage points.[19] At the time of the follow-up study, a randomly selected sample of husbands of WHT participants was also surveyed to assess the diffusion of the low-fat intervention from the participants to their spouses and to investigate the mechanism of this transfer. Specifically, the purpose of this study was to determine whether the husbands of intervention

group women had reduced their dietary fat intake, compared with husbands of control group women, and to assess whether dietary change was due to the men's active pursuit of healthier eating habits or to their passive acceptance of their wives' new eating patterns.

Methods

The Women's Health Trial

The WHT began in three clinical sites in April 1985; however, despite successful recruitment and an effective intervention, the trial was canceled in March 1988 because of concerns about the costs and benefits of a large low-fat intervention trial. The details of the first phase of the trial and of the intensive low-fat dietary intervention have been reported elsewhere.[22,23] Briefly, the WHT participants were healthy women aged 45 to 69 years who, after being screened for eligibility, were randomly assigned to the dietary intervention group or the control group. The intervention women attended small-group sessions, which met weekly and then monthly for a period of 5 to 37 (mean of 15.5) months. The major goal was to reduce total dietary fat intake by intervention women to 20% of baseline kilocalories by means of nutrition education and behavior modification strategies. The objective in the control group was to intervene as little as possible with the participants' normal diet while collecting follow-up medical and dietary data.

Husbands of participants were not formally included in the intervention and very few attended educational sessions, but all intervention husbands were invited to attend infrequent (e.g., annual) group activities. Intervention women were encouraged to cook low-fat meals for their families, but they were also provided with methods for incorporating their low-fat diet as a subset of the regular family meals.

Sample Selection

WHT intervention women and their husbands were eligible for the follow-up study if the women had begun intervention sessions before November 1, 1987. Control group women and their husbands were eligible if the women had been randomized before November 1, 1987. The cutoff date allowed intervention women to complete a minimum of eight dietary education sessions before the announcement of the end of the trial. Women who were diagnosed with breast cancer during the trial (and their husbands) were not eligible for the follow-up study. From 1650 eligible WHT women, 525 intervention women and 525 control women were randomized into the follow-up study; of these, 793 were married at baseline. Two hundred twenty-five intervention husbands and 225 control husbands, divided equally among the three clinical sites, were randomly selected for this study. Men were eligible to participate only if they were married to and living with a WHT participant at baseline and at follow-up.

Data Collection

Data collection was conducted between January and December 1989, and was randomly distributed over a period of 6 to 20 (average of 12) months after active WHT intervention had ended. In addition, data collection was equally distributed across months among intervention and control groups. Dietary data, food patterns, health information, and demographic data were collected by means of mailed, self-administered questionnaires. Twelve weeks after the initial mailing, telephone interviews were attempted for all participants who had not yet refused or responded to the previous two mailings and reminder telephone call.

A 100-item semiquantitative food frequency questionnaire was completed by the women and their husbands and was used to estimate average daily intake of energy, fat, and other nutrients. The questionnaire, nutrient data base, and computer software program for analysis of the questionnaire were modifications of those developed by Block and colleagues at the National Cancer Institute (NCI).[24,25] Foods such as frozen yogurt and low-fat cheeses were added to the food frequency questionnaire to enhance the assessment of low-fat food selection. In addition, to reflect current dietary patterns, the reference time period for the food frequency questionnaire was "over the last 3 months."

For the analyses presented here, several of the items from the husbands' health questionnaire were combined into scales. An indicator of socioeconomic status was computed, on the basis of Hollingshead's two-factor index of social position,[26] by combining scales for self-reported education and occupation. A knowledge score was calculated by summing the number of correct answers to whether or not 14 food items were high in fat. The attitude score was the average of the responses (scored from 1, "disagree strongly," to 5, "agree strongly") to two items on diet and chronic disease: "A low-fat diet can reduce your risk of heart disease" and "A low-fat diet can reduce your risk of cancer." A summary score representing positive changes in eating patterns was created by summing the number of high-fat foods that a husband reported eating less often and the number of low-fat foods that he reported eating more often. A higher dietary change score (range 0 to 12) indicated a greater number of fat-reducing dietary changes.

Response Rates and Missing Data

Four hundred thirty-six of the 450 randomized husbands were eligible to participate in the follow-up study: 6 intervention and 7 control husbands were excluded because the wives reported they were no longer married (i.e., that they were separated, divorced, or widowed); 1 control husband was excluded because his wife had developed breast cancer after the end of the WHT and dietary changes might have followed the diagnosis. Seventy-one percent (156/219) of the eligible intervention husbands and 68% (148/217) of the eligible control husbands completed the mailed questionnaires. Of those who did not complete the mailed questionnaires, about half of the intervention husbands (n = 35) and the control husbands (n = 32) completed a shortened telephone version of the health questionnaire that included questions on weight and eating patterns.

Statistical Analysis

Differences between intervention and control group husbands were examined with Student's t test for continuous variables, with a chi-square test for categorical variables, and with the Mantel-Haenszel test for trend for ordered categorical variables.[27] With the exception of nutrient density values, dietary variables were log transformed to normalize their distribution and then untransformed for presentation in the tables. Regression analyses with percentage of energy from fat as the dependent variable were performed to adjust for potential confounding factors. Regression models were also used to determine predictors of a lower-fat diet while controlling for an intervention-group effect, and for effect modification by intervention group (interaction between each factor and group).[28] We explicitly tested factors that we hypothesized to be intermediate between the wife's participation in the intervention (group effect) and any resulting change in the husband's dietary fat intake by fitting regression mod-

els to predict husbands' fat intake based on each factor plus the group effect (see Table 5, note a).

Results

The husbands of the two groups of WHT participants (intervention and control) were similar in terms of reported demographic characteristics and health status at follow-up (Table 1). Most of the men were between 50 and 69 years of age, well-educated, healthy, above the middle level of Hollingshead's 5-point scale of socioeconomic status,[26] and working at least part-time. Significantly fewer intervention husbands than control husbands smoked cigarettes at follow-up ($P < .01$). There were no differences between groups in the number of months the wives participated in WHT (a mean of 15 months) or in the time between the end of the trial and follow-up (a mean of 12 months) (data not shown).

The husbands' mean daily intake of energy, fat, and other major nutrients, as estimated from a self-administered food frequency questionnaire, are summarized in Table 2. An average of 1 year after the trial ended, intervention husbands consumed significantly fewer kilocalories and less dietary fat and cholesterol than did control husbands (all Ps $< .01$). As a percentage of energy intake (%en), total dietary fat intake was 32.9% for intervention husbands vs 36.9% for control husbands ($P < .001$). This difference was similar across the three geographic locations and did not change when adjusted for smoking habits or history of chronic diseases (data not shown). There were no differences between groups in dietary fiber consumption or in the ratio of polyunsaturated (linoleic) to saturated fatty acids.

The husbands were asked about how their consumption of selected foods and food groups had changed since their wives entered the WHT (Table 3). Significantly more intervention than control husbands reported eating less of each high-fat food (all Ps $< .01$), but there were no significant differences between groups in increased consumption of foods promoted as healthy. The decreased consumption of foods high in both saturated and polyunsaturated fat is consistent with the WHT goal of lowering total fat. The summary dietary change score differed substantially between intervention and control group husbands ($P < .001$), indicating that intervention husbands made significantly more dietary changes in the recommended direction (e.g., decreasing high-fat foods) than did the control husbands.

Mean recalled body weight at the time their wives entered WHT did not differ between intervention and control group husbands (Table 4). At follow-up, however, intervention husbands had a significantly lower mean reported weight than did control husbands ($P < .05$). Consistent with the lower estimated energy intake by the intervention husbands, weight change between the two time periods was greater in the intervention group than in the control group ($P = .06$).

To understand whether the reduction in fat intake among intervention husbands was due to an active change in the husbands' knowledge, attitudes, and behaviors or to a passive acceptance of low-fat meals consumed at home, we compared measures of these factors between groups (Table 5). In addition, we tested these variables as intermediate factors between the WHT intervention and a change in the husbands' fat intake; an "intermediate" would be expected to significantly predict husbands' fat intake (β_1) and to reduce the group effect (β_2) (from a coefficient of 3.96 in a model with group alone). Lastly, we anticipated that some of these variables would have a greater effect on dietary fat intake among intervention husbands than among control group husbands; however,

there was no evidence of effect modification for any of the measured factors (data not shown).

Although knowledge of foods high in fat was significantly greater among intervention husbands than among control group husbands, knowledge did not have an effect on overall fat intake, nor did it explain the group effect (Table 5). Conversely, the husbands' attitude toward diet and disease was strongly associated with their percent of energy from fat, but there was no difference in attitude between intervention and control group husbands. The number of meals that a husband and wife shared each week had a significant, independent effect on the husband's fat intake; however, the number of meals shared did not reduce the intervention effect. There were no differences between the intervention and control groups in the reported frequency with which husbands chose low-fat foods when not eating with their wives. Although it was strongly associated with husbands' percentage of energy from fat across both groups of men, after we adjusted for intervention group this variable made no difference in the coefficient for group effect (β_2).

As expected, a husband's fat intake was positively associated with his wife's percentage of energy from fat ($P < .001$). A correlation of 0.34 was found between a husband's percentage of energy from fat and his wife's ($P < .001$, data not shown); this was a high correlation, considering the degree of measurement error in both variables. Of all the factors listed in Table 5, only the wife's fat intake substantially explained the intervention group effect (β_2 was reduced and no longer significant). In addition, the husbands of intervention group women who reported fixing separate meals for their families consumed a diet 3.6 (absolute) percentage points higher in fat (as %en) than intervention group husbands whose wives did not prepare separate meals ($P < .01$).

Discussion

We assessed the transfer of dietary habits from wives to husbands 1 year after the wives' participation in an intensive low-fat dietary intervention had ended. The intake of total dietary fat and of each type of fat was significantly lower among the husbands of the intervention group women than among the husbands of control group women. Nutrient estimates from a self-administered food frequency questionnaire indicated that intervention husbands consumed 32.9%en as fat, vs 36.9%en for control husbands. The mean fat intake by control group men is in close agreement with data from the National Health and Nutrition Examination Survey II (1976 to 1980),[29] which found a fat intake of approximately 37%en for men over 45 years of age, and with the 38%en for men aged 18 to 65 years reported by Stephen and Wald[30] in a combined analysis of 171 studies that obtained individual dietary data (1980 to 1985). Thus, the dietary fat intake (as %en) of the participants in this study appears to be similar to that reported elsewhere for representative men in this country.

Although the 4-percentage-point group difference in percentage of energy from fat (32.9% vs 36.9% for intervention and control husbands, respectively) is only half the 8-point difference observed in the WHT women at follow-up (27.7% vs 35.1%),[19] it represents considerable progress toward the 30%en from total fat recommended by the NCI and other national health organizations. Furthermore, the magnitude of the group difference is similar to that reported by some large-scale dietary trials that intervened directly with high-risk men.[31,32] For example, the Multiple Risk Factor Intervention Trial (MRFIT) reported 34%en as fat in the special intervention group (meeting the study goal) vs 38%en in the usual-care group; these figures were mean percentages of energy from fat averaged from follow-up data for years 1, 3, and 6.[31]

The group difference in fat intake found in the present study is twice the 2-percentage-point difference (34%en vs 36%en) found between intervention and control husbands during the WHT.[16] Several reasons for the larger difference in the follow-up study have been considered. Different instruments were used to measure dietary intake, and the current version (Block, NCI)[24] was modified to be more sensitive to lower fat intake. Greater measurement error in the dietary assessment made during the trial may have masked a larger effect. In addition, acceptance of low-fat dietary patterns by the husbands may occur slowly, or sufficient knowledge of the diet to accurately complete a food questionnaire may be acquired over time; therefore, greater differences would be expected after an extended time period.

The changes in food consumption patterns among the husbands in this study reflect the WHT intervention[23,33] more than the healthy eating habits recommended for general health and heart dis-

ease prevention that have been widely publicized over the past few decades. While all of the foods listed in Table 3 represent foods for which the NCI, the American Heart Association, and other health organizations have recommended changes,[1] the foods for which consumption was significantly different between intervention and control husbands were ones associated with lowering total fat (saturated and unsaturated fatty acids) in the diet. Correctly identifying foods high in polyunsaturated fat (peanut butter and margarine) was also more common among intervention than control men, suggesting some transfer of knowledge from intervention wives concerning a diet low in total fat. There were, however, no differences between groups in other promoted healthy eating habits, such as increased intake of high-fiber fruits, vegetables, and whole grains. This increases our confidence that the changes in the dietary habits of intervention group husbands were attributable to the WHT low-fat intervention.

Our finding that an intervention given to one family member can have a positive effect on the health behaviors of others supports the results of several other studies.[6,17,18] In studies relevant to the design of this study, Zimmerman et al.[17] and Sexton et al.[18] studied wives of men who participated in intervention trials. Zimmerman and colleagues[17] compared the effects of a work-site health promotion program for fire fighters on 32 intervention group wives compared with 9 wives of fire fighters who had not yet received the program. While no statistically significant differences in the wives' health habits were found, healthy dietary changes were made in the expected direction. Sexton et al.[18] assessed risk factor changes in 220 wives of MRFIT special-intervention (SI, n = 80) and usual-care (UC, n = 140) participants. Beneficial effects of the MRFIT intervention were suggested by lower food-record ratings (indicating greater adherence to the MRFIT eating plan), higher diet-knowledge scores, and a lower mean weight and serum cholesterol among the SI wives. However, only 36% of the invited SI wives and 64% of the UC wives participated in the study, and self-selection may have led to greater between-group differences than would otherwise be the case. The results of these studies and our research, however, do suggest the potential importance of the effects on other family members of one member's participation in a health-oriented intervention program.

The previous report on WHT husbands[16] made no direct attempt to investigate whether the lower fat intake by intervention group husbands was due to their passive acceptance of low-fat foods being served by their wives or to the husbands' active participation and internalization of their wives' new eating patterns. In the current study we were able to address this question more directly, and a number of our findings suggest that the former case is more likely (Table 5). First, there was no difference between the two groups of husbands in their responses as to whether they chose low-fat foods when not eating with their wives. Second, our hypothesized intermediate variables, knowledge of foods high in fat and attitude regarding diet and disease prevention, did not appear to explain the intervention effect. Finally, the wife's attitude and behavior were among the most important predictors of a husband's dietary fat intake. This is consistent with findings by Schafer,[34] who reported that a wife's influence, and a husband's perception of his wife's influence, were related to better diets for both husbands and wives. The women in our study had the primary responsibility for family meal preparation: over 70% of the women in both groups reported having at least 90% of the responsibility for planning, purchasing, and preparing family meals. In addition, we found

[a]Regression model: Percentage of energy intake (%en) from fat = $\alpha + \beta_1$ factor + β_2 group. Limited to the 304 participants who completed the food frequency questionnaire.
[b]Based on total number of right answers to whether or not 14 food items were high in fat.
[c]The average of responses to two items on diet and health; a high score is consistent with the belief that diet improves health. Scale: 1 = disagree strongly, 2 = disagree somewhat, 3 = don't know, 4 = agree somewhat, 5 = agree strongly.
[d]Scale: 1 = rarely or never, 2 = sometimes, 3 = often, 4 = usually or always.
[e]As reported by wife, intervention women only; coded 1 = No, 2 = Yes.

a high correlation between a husband's percentage of energy from fat and his wife's. Similarly, Lee and Kolonel found high correlations in nutrient intake among 1428 married couples[11] and good correspondence for food items most likely to be consumed at home among another sample of 281 husband-wife pairs.[12] In summary, the effect of the WHT low-fat dietary intervention on husbands seemed to be accomplished through the behavior of their wives. The above findings taken together suggest that the lower fat intake reported by the intervention group husbands was more likely due to their passive acceptance of lower-fat foods being served at home than to their active participation in their wives' new eating patterns.

A number of limitations need to be considered in interpreting the results of this study. No data were obtained from the husbands at the time their wives entered the WHT. However, because of the randomization of women into intervention and control groups and the random selection of women and their husbands for this follow-up study, the baseline characteristics of the intervention and control group husbands were assumed to be comparable. With the exception of smoking, there were no differences in the husbands' self-reported demographic or health characteristics at the time of this study, and controlling for smoking in a multiple regression model did not change the between-group difference in percentage of energy from fat. If we are correct in assuming baseline similarities between groups, a greater reduction in dietary fat intake occurred among intervention husbands than among control husbands.

Social desirability bias could have influenced intervention group husbands to report lower fat intakes. We also recognize that bias may be present in the husbands' self-reported dietary changes, especially as they relate directly to the WHT intervention. However, because the husbands were not active participants in the WHT dietary intervention, they would be less likely than their wives to be influenced by these biases.

There is also a potential for bias due to the self-selection of husbands who completed the study questionnaires. Seventy percent of eligible intervention husbands completed the mailed questionnaires, and half of the 30% nonrespondents (35 intervention and 32 control husbands) completed a shorter questionnaire by telephone. To evaluate the potential selection bias, we compared the dietary change scores (see Table 3) of mail respondents with those of telephone respondents. The magnitude of the difference between mail and telephone respondents was identical for intervention and control groups, indicating that there was no differential bias between groups.

The women who participated in the WHT were a group of dedicated and highly motivated women, which limits the generalizability of our findings. The changes in dietary fat intake made[22,23] and maintained by the intervention women[19] may be greater than could be expected in a less select population. Therefore, the magnitude of change seen in the husbands' diets may also be greater than could be expected from a less intensive intervention. On the other hand, the observed difference in fat intake between the two groups may be less than the actual difference. In the follow-up study, we found that the low-fat dietary behaviors most easily maintained by the WHT intervention women were the substitution of specially manufactured low-fat foods and the modification of commonly used foods to be lower in fat.[20] Because these dietary changes are not likely to be noticed by most husbands, the changes in dietary fat intake may be underreported, indicating a potentially larger intervention group–control group difference in percentage of energy from fat than was measured. Furthermore, the group difference may also have been underestimated because of the measurement error inherent in the food frequency instrument and because of the instrument's insensitivity to low fat intake.[19,33]

We conclude that the WHT dietary intervention program for motivated women had a significant effect on nonparticipating spouses at no additional cost. The mechanism of this effect appeared to be passive change brought about by the

success of the WHT intervention and the husbands' acceptance of low-fat foods being served at home. The 34%en from fat consumed by intervention husbands is a substantial move toward the dietary goal of 30%en recommended by many US health organizations. Although this was an intensive intervention with a select group of motivated women, an intervention directed at, or including, the family member with food purchasing and preparation responsibilities could be a cost-effective and broad-reaching approach to public health dietary change programs. □

Weight Loss Attempts in Adults: Goals, Duration, and Rate of Weight Loss

David F. Williamson, PhD, Mary K. Serdula, MD, Robert F. Anda, MD, Alan Levy, PhD, and Tim Byers, MD

ABSTRACT

Objectives. Although attempted weight loss is common, little is known about the goals and durations of weight loss attempts and the rates of achieved weight loss in the general population.

Methods. Data were collected by telephone in 1989 from adults aged 18 years and older in 39 states and the District of Columbia. Analyses were carried out separately for the 6758 men and 14 915 women who reported currently trying to lose weight.

Results. Approximately 25% of the men respondents and 40% of the women respondents reported that they were currently trying to lose weight. Among men, a higher percentage of Hispanics (31%) than of Whites (25%) or Blacks (23%) reported trying to lose weight. Among women, however, there were no ethnic differences in prevalence. The average man wanted to lose 30 pounds and to weigh 178 pounds; the average woman wanted to lose 31 pounds and to weigh 133 pounds. Black women wanted to lose an average of 8 pounds more than did White women, but Black women's goal weight was 10 pounds heavier. The average rate of achieved weight loss was 1.4 pounds per week for men and 1.1 pounds per week for women; these averages, however, may reflect only the experience of those most successful at losing weight.

Conclusions. Attempted weight loss is a common behavior, regardless of age, gender, or ethnicity, and weight loss goals are substantial; however, obesity remains a major public health problem in the United States. (*Am J Public Health.* 1992; 82:1251–1257)

Introduction

Voluntary weight loss is a common practice in the United States and appears to be increasing in prevalence. In national surveys conducted between 1950 and 1966, about 7% of men and 14% of women reported that they were trying to lose weight.[1,2] A 1978 survey found that 16% of adults were trying to lose weight.[1,3] More recent data from the 1985 National Health Interview Survey suggest that the prevalence of attempted weight loss has increased substantially; about 25% of men and 45% of women reported that they were trying to lose weight.[4]

Although attempts to lose weight are common, data on specific aspects of this behavior in the general population are limited.[1] Much of our knowledge about voluntary weight loss comes from clinical studies of self-selected subjects, many of whom are severely obese. The findings from such studies may produce biased estimates if applied to the general population.[1,5,6] The purpose of this study is to describe the age- and race-specific prevalence of weight loss attempts, the goals and duration of such attempts, and the rate of weight loss achieved in a population-based, multistate health practices survey.

Methods

Data Source

Data for this analysis are from the 1989 Behavioral Risk Factor Surveillance System (BRFSS) cross-sectional survey of 39 states and the District of Columbia. The BRFSS is a joint effort between the Centers for Disease Control (CDC) and participating state health departments. The BRFSS is a random-digit-dialed telephone survey of each state's noninstitutionalized civilian population aged 18 years and older with telephones. Each participating state conducts approximately 100 interviews per month throughout the year, using a multistage cluster design.[7] All states use an identical core questionnaire, and CDC staff provide standardized training in survey operations. In 1989 the median state response rate (the ratio of completed interviews to the sum of completed interviews and refusals) was 82%. A detailed technical description of the BRFSS has been presented elsewhere.[8]

The BRFSS telephone interview included 65 core questions and took about 25 minutes to administer. The questions on weight control practices were asked of all respondents near the middle of the interview, and followed questions on seat belt use, hypertension, and physical activity. Questions on current self-reported weight and height were asked at the end of the interview.

Weight Control Status

Respondents were first asked, "Are you now trying to lose weight?" If they answered no, they were asked, "Are you now trying to maintain your current

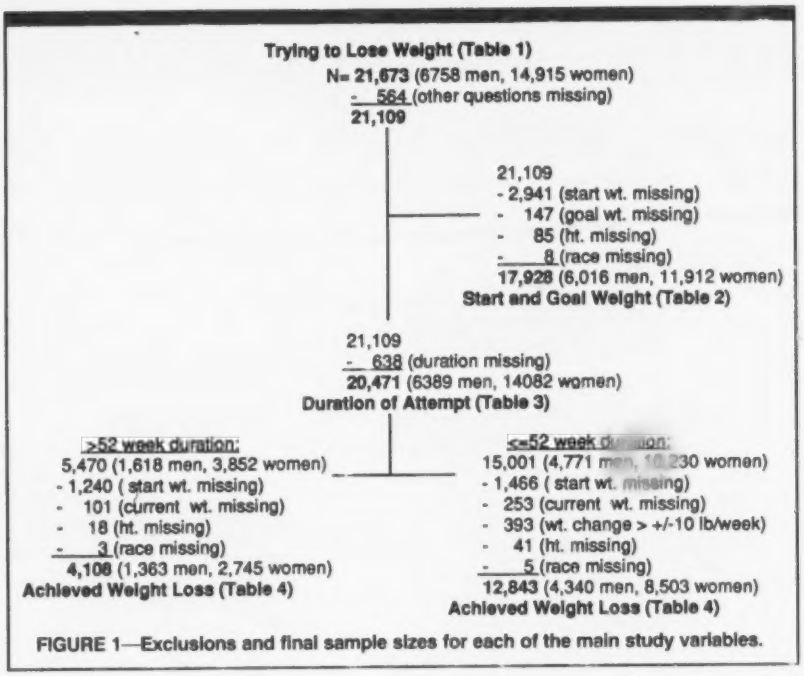

FIGURE 1—Exclusions and final sample sizes for each of the main study variables.

weight, that is, to keep from gaining weight?" Persons who responded no to this question were considered to be doing nothing about their weight. Of the 66 867 respondents who completed the telephone interview, 153 (0.2%) did not answer yes or no to the question of whether they were trying to lose weight, 1680 (2.5%) reported that they were trying to gain weight, and 397 (0.6%) did not answer the question as to whether they were trying to maintain their weight. This left 64 637 persons who could be classified into one of the three groups according to their current weight control status: trying to lose weight (n = 21 673; 33.5%), trying to maintain weight (n = 18 253; 28.2%), or doing neither (24 711; 38.3%).

Duration of Weight Loss Attempt

Those who reported that they were trying to lose weight were asked, "About how long ago did you begin your current attempt to lose weight?" We expressed duration of attempted weight loss in terms of weeks; in some analyses persons who reported trying to lose weight for more than 52 weeks were combined with those who reported that they were "always trying to lose weight" and were analyzed as a separate category of duration.

Weight Loss Goal

Persons trying to lose weight were next asked, "About how much did you weigh when you began your current attempt to lose weight?" and "How much would you like to weigh?" These questions were used to estimate the respondents' mean weight at the start of their weight loss attempt and their mean goal weight. We computed the difference between the starting weight and the goal weight as the weight loss goal and expressed both in pounds and in relative terms by dividing the weight loss goal by the starting weight to obtain a percentage weight loss goal. For some analyses we categorized respondents according to four categories of body mass index (BMI: kg/m^2): < 26, 26 to < 30, 30 to < 35, ≥ 35. We classified persons with a BMI ≥ 30 as obese.[9]

Achieved Weight Loss

We computed the difference between the starting weight and the current weight as the achieved weight "loss" (this included some respondents who had a net gain in weight). The achieved weight loss was computed separately for durations > 52 weeks (including those who reported "always trying to lose weight") and for durations of ≤ 52 weeks. For the respondents who reported a duration of ≤ 52 weeks, we also estimated the rate of achieved weight loss, expressed as pounds per week. We considered a weight change of more than ±10 pounds per week to be biologically implausible, and the records of persons who reported such high rates were excluded. We also estimated the prevalence of achieved weight loss of more than 2 pounds per week, a rate that is considered potentially harmful.[10,11]

Final sample sizes. This analysis focuses primarily on the 21 673 respondents who reported that they were currently trying to lose weight. One state did not ask any of the questions on duration, starting weight, or goal weight; respondents in that state (n = 564, 2.6% of the total) were excluded from further analyses, leaving 21 109 respondents to answer the remaining questions. Subsequent exclusions and final sample sizes for each of the main study variables are shown in Figure 1.

Statistical analysis. We report all results separately for men and women. Because of the large sample sizes, we have not emphasized statistical testing; however, *P* value estimates are given in the accompanying tables. In some analyses we computed age- and race-specific prevalence estimates and their 95% confidence limits (CL).[12] We used the Pearson chi square to test for homogeneity of the prevalence estimates across age and race strata. Weighted least squares estimation was used to statistically test for interaction between age and race on the prevalence estimates.[13] For those who reported trying to lose weight for 52 weeks or less, we computed the age- and race-specific median duration (in weeks) of weight loss and the 95% CL.[14] Age- and race-specific mean starting and goal weights and mean weight loss goal with 95% CL were estimated by analysis of variance,[13] which also adjusted for height. Race-specific estimates were also adjusted for age, as were estimates of achieved weight loss and rate of weight loss. Although a higher proportion of Whites (55%) than of Blacks (41%) and Hispanics (44%) had education beyond high school, further adjustment for education had little effect on race-specific estimates.

Results

The mean age of men respondents was 44 years; 85% were White, 63% were married, and 53% had more than 12 years of education. Their mean BMI was 25.7, which is comparable to the most recent national estimate of mean BMI in men of 25.3.[15] The mean age of women respondents was 46 years; 84% were White, 53% were married, and 47% had more than 12 years of education. Their mean current BMI was 24.2, somewhat lower than the national estimate of 25.0.[15]

Weight Control Status

About 25% of the men (95% CI = 24%, 26%) reported that they were currently trying to lose weight (Table 1). The peak prevalence of trying to lose weight occurred among those aged 40 to 49 years (30%) and among Hispanics (31%). BMI, however, had a much stronger relationship to the prevalence of trying to lose weight than did age or ethnicity. The prevalence increased more than fivefold between men with a BMI of < 26 (13%) and those with a BMI of > 35 (65%).

Among women, 39% (95% CI = 38%, 40%) reported that they were currently trying to lose weight (Table 1). The association with age was similar to that seen in men; in women, however, ethnicity was unrelated to the prevalence of trying to lose weight. For women as for men, BMI had the strongest relationship to the prevalence of trying to lose weight.

TABLE 1—Weight Control Status Prevalence (Expressed as Percentages) by Selected Characteristics of Respondents to the 1989 Behavioral Risk Factor Surveillance Survey

26–29.9	58.5	19.1	22.4
30–34.9	63.9	17.4	18.7
≥35	68.6	12.8	18.6
Total	39.3	27.9	32.3

Note. Each percentage is a percentage of its row. Percentages may not add to 100 because of rounding. The chi-square statistics apply only to persons trying to lose weight and are a test for homogeneity of the prevalences across levels of each characteristic. BMI = body mass index.

[a] χ^2 (df, 5) = 319.6, $P < .001$.
[b] χ^2 (df, 3) = 24.4, $P < .001$.
[c] Of those reporting Hispanic origin, 51.0% were from the following states: Arizona (5.7%), California (14.0%), New Mexico (11.0%), Texas (9.5%), Florida (5.8%), and New York (5.0%).
[d] χ^2 (df, 3) = 3942.4, $P < .001$.
[e] χ^2 (df, 5) = 1039.2, $P < .001$.
[f] χ^2 (df, 3) = 6.1, $P < .11$.
[g] χ^2 (df, 3) = 3157.7, $P < .001$

Weight Loss Goal

Among men trying to lose weight, the mean weight at the start of the weight loss attempt was 209 pounds; the mean goal weight was 178 pounds, for a mean weight loss goal of 30 pounds (13.4% of the starting body weight) (Table 2). The youngest age group (18 to 29 years) had lower mean starting and goal weights than did the older age groups. Compared with Whites, Black men had higher mean starting and goal weights, but they also had a slightly higher mean goal weight loss, as did Hispanic men.

Among women trying to lose weight, the mean starting weight was 164 pounds; the mean goal weight was 133 pounds, for a mean weight loss goal of 32 pounds (17.6% of the starting weight) (Table 2). As was true for men, the youngest group had lower mean starting and goal weights than did the older groups. Among women, there were substantial differences in weights and weight loss goals between Whites and Blacks and, to a lesser degree, between Whites and Hispanics. Black women had a 19-pound-heavier mean starting weight and an 11-pound-heavier mean goal weight, but an 8-pound-greater mean weight loss goal, than did their White counterparts.

We found a strong association between gender and starting weight and goal weight (expressed as BMI) (data not shown). Among those in the starting BMI category of 30 to 34.9, 39% of men, compared with 80% of women, had a weight loss goal that would place them in the leanest goal BMI category (< 26). Among those in the heaviest starting BMI category (≥ 35), 19% of men, compared with 59% of women, wanted to end up in the leanest category. Thus, obese women are two to three times more likely than obese men to have a weight loss goal that would place them in the leanest body weight category.

Duration of Weight Loss Attempts

Among men trying to lose weight, the prevalence of long-term weight loss attempts (defined as trying to lose weight for more than a year or "always trying to lose weight") was 25% and was directly related to age (Table 3). There was a mod-

CI = confidence interval.
[a]Percentage of starting body weight.
[b]Statistically different ($P < .05$) from 18–29 age group and from Whites.

est relationship between race and long-term weight loss attempts; prevalence ranged from 23% among Black men to 31% among men of "other" race. If the prevalence of long-term weight loss attempts is applied to the total sample of men, then 6% (0.253 × 0.252 × 100) of all men were trying to lose weight for more than a year.

Among women trying to lose weight, the prevalence of long-term weight loss attempts was 27%, which was similar to that for men (Table 3). There was also a consistent increase in prevalence with increasing age. In contrast to men, however, for women there was a strong association between race and the prevalence of long-term weight loss attempts, which ranged from 18% among Blacks to 29% among Whites. In terms of the total sample, 11% of all women were trying to lose weight for more than a year.

We also estimated the median duration of the current weight loss attempt for those trying to lose weight for a year or less (data not shown). Among men, the median duration of the current weight loss attempt was 6 weeks (95% CL = ± 0.3 weeks). The median duration increased with increasing age, from 4 weeks among those in the 18 to 29 age group to 12 weeks among men in the 70+ age group. The median duration was 2 weeks shorter for White men than for men of other races. Among women, the median duration of the current weight loss attempt was 4 weeks (95% CL = ± 0.2 weeks). The median duration was 4 weeks for women younger than 50 years of age and rose to 8 weeks for women aged 50 and older. Women of "other" race had a median duration of 8 weeks, compared with 4 weeks for the three racial groups.

Achieved Weight Loss

Among men trying to lose weight for more than 1 year, the mean achieved weight loss was 12 pounds (Table 4). There was substantial variation in weight loss across age categories, with the highest weight loss (18 pounds) occurring in those aged 18 to 29 years and the smallest loss (10 pounds) occurring in those aged 30 to 39 years. There was a strong relationship between race and achieved weight loss; Hispanic men reported the largest weight loss (19 pounds) and men classified as "other" race reported the smallest loss (11 pounds).

Among men trying to lose weight for 1 year or less, the mean achieved weight loss was 10 pounds and varied strongly with age, ranging from 9 pounds for men aged 30 to 39 to 12 pounds for men aged 60 to 69 (Table 5). The mean rate of weight loss was 1.4 pounds per week; this figure also varied substantially with age, ranging from a loss of 1.6 pounds per week for men aged 18 to 29 to 0.9 pounds for men aged 70 and older. There was little relationship between race and the rate of weight loss in men.

Among women who reported trying to lose weight for more than a year, the mean achieved weight loss was 8.8 pounds (Table 4). As was seen with men, the largest loss (12 pounds) occurred in women aged 18 to 29 and the smallest loss (8 pounds) was among women aged 40 to 49. There was little difference by race in achieved weight loss for women.

Among women trying to lose weight for a year or less, the mean achieved weight loss was 8 pounds and was unrelated to age (Table 5). However, the achieved weight loss was nearly 1.5 pounds lower for Black women (7.2 pounds) than for White women (8.6 pounds). The mean rate of weight loss for women was 1.1 pounds per week and was inversely related to age, ranging from a loss of 1.1 pounds per week for women aged 18 to 29 to a loss of 0.7 pounds per week for women aged 70 years and older. Race was unrelated to the rate of weight loss in women.

The prevalence of a rate of achieved weight loss in excess of 2 pounds per week was 25% for men and 18% for women (data not shown). The prevalence was consistently 5 to 10 percentage points higher for men than for women in all age groups and was inversely related to age. The prevalence ranged from a high of 31% for men aged 18 to 29 years to a low of 10% for women aged 70 years and older. The prevalence was not related to race for either men or women.

Discussion

Using data from a geographically and ethnically diverse sample of adults in the general population, we found that approximately 25% of men and 40% of women were trying to lose weight, with the peak prevalence occurring among persons in their 40s. These findings are similar to those from a recent nationally representative in-person survey of health practices, in which 25% of men and 44% of women reported that they were currently trying to lose weight.[4]

Approximately 25% of both men and women who were currently trying to lose weight could be defined as long-term dieters. Thus, in the total sample, the prevalence of long-term dieting is about 6% of all men and 11% of all women. In a national 1985 Gallup Poll,[16] 16% of women considered themselves "perpetual dieters." This higher estimate may have been due to different definitions of long-term dieting. We found no published estimates of the prevalence of long-term weight loss attempts by men.

The average person trying to lose weight wanted to lose about 30 pounds. This figure is similar to that found in earlier studies of self-selected samples. Ureda[17] found that the median weight loss goal of men and women volunteers in a university-based weight loss program was 35 pounds, and Muhlenkamp and Nelson[18] reported an average weight loss goal of 33 pounds in a sample of clients of a commercial weight loss program (gender not given).

In absolute terms, the weight loss goal was very similar for both men and women, but relative to their starting weights, the goal of women was about one-third higher than that of men (17% vs 13% of body weight). The apparent desire of women to lose a larger proportion of their weight was also reflected in the relationship between starting BMI and goal BMI: women in the heaviest BMI categories at the start of their weight loss attempt were two to three times more likely than men to want to end up in the leanest BMI category. We found no published studies that directly compared weight loss goals of men and women. However, our findings support the view that women are under greater pressure than men to lose weight.[19]

The achieved weight loss in this study was similar for long-term dieters and shorter-term dieters. Regardless of duration, the average man had lost 10 to 12 pounds and the average women had lost 8 to 9 pounds. It may be that long-term dieting is simply a marker for difficulty in losing weight. It is also possible that long-term dieters are more likely to lose and regain some of their weight cyclically during any one attempt. However, because our study had information only on starting and current weight, the true underlying variability in weights of long-term dieters may have been masked.

The higher amount and higher rate of achieved weight loss reported by men are consistent with the results of clinical studies[20,21] and are a function of the higher average starting weights of men.[22] After

adjusting for starting BMI, we found that the rate of weight loss for men and women was identical at 1.3 pounds per week.

Ethnicity had a modest association with the prevalence of attempted weight loss for men, with Hispanic men reporting the highest prevalence. Black and Hispanic men also tended to weigh more than White men when they started their attempt to lose weight. After controlling for duration, we found that the rate of weight loss was nearly the same for all ethnic groups of men. Previous studies suggest either that there is no difference in "dieting behavior"[23] between Hispanic and Anglo men or that Hispanic men are less inclined to diet to lose weight.[24] Our finding of a higher prevalence of attempted weight loss by Hispanic men may reflect the higher socioeconomic status of Hispanics from telephone-owning households.

Among women, however, we found no association between the prevalence of attempted weight loss and ethnicity. A lower prevalence of attempted weight loss has been proposed as a potential cause of the higher levels of obesity in Black women.[25] Although studies done in the 1960s suggested that Black women were less likely than White women to try to lose weight,[25] more recent studies indicate that there is less difference between Black and White women in the prevalence of attempting to lose weight.[25–28] We did find differences between White and Black women in weight loss goals. Although Black women had higher starting and goal body weights than did White women, Black women still wanted to lose about 8 pounds more than did their White counterparts. We also found ethnic differences in women in the prevalence of long-term attempted weight loss; White women were nearly 60% more likely than Black women to report that they had been trying to lose weight for a year or more. Black women reported lower achieved weight losses than did White women, which was also observed in earlier studies.[29,30] After we adjusted for duration, however, the rate of weight loss for Black and White women was identical. Taken together, our findings do not suggest that Black or Hispanic women are markedly different from White women in their weight loss behavior.

Although 39 states and the District of Columbia were included in the sample, this survey was not designed to represent the US population. The sample was also limited to telephone-owning households; although only about 4% to 7% of US households do not own telephones, weight control practices may differ depending on telephone ownership. This sampling bias may be particularly important for ethnic minorities, for whom telephone ownership is lower than in the general population.[31] We know of no study that has examined differences in weight control practices between persons from households with and without telephones. Previous studies have generally reported that there are only modest differences in other health practices between persons from households with telephones and those without telephones.[31,32]

This study had a survey nonresponse rate of 18%. In a study of nonrespondents to a general-topic telephone survey, however, it was found that the survey's population estimates were only slightly altered by including data collected from the initial nonrespondents.[33] In addition, a recent study of the BRFSS found no statistically significant differences in the mean BMI or in the prevalence of current weight loss attempts between initial responders and nonresponders.[34]

A related issue is that of item nonresponse, which was highest for the question on weight at the start of the weight loss attempt (see Figure 1). It may be that those who had very high weights were less willing to answer this question because of embarrassment, or because they were unsuccessful at losing weight. If this was true, then our estimates of mean starting weights may be too low. Differential item nonresponse may also account for the similarity in achieved weight loss between long-term and short-term dieters. For long-term dieters, nearly 23% of starting weights were missing, compared with 10% for short-term dieters. Hence, our estimates of achieved weight loss must be viewed cautiously.

In this study weight and height were self-reported. Self-reports produce downwardly biased estimates of overweight,[35] and this bias may be greater in telephone surveys.[36] Hence, some persons were probably misclassified in lower BMI categories. Past body weight is generally reported with reasonable accuracy, even

when the recall period is as long as 40 years.[37,38] We believe, however, that persons who are attempting to lose weight are more likely than the general population to know their current and previous weights.

Our study suggests that nearly one of every three adults in the United States is currently trying to lose weight, making voluntary weight loss one of the most common health-related practices in the United States today. Although more than $30 billion is spent annually on weight loss,[39] the long-term health effects of weight loss remain unclear.[40,41] Thus, it is important to provide better information to the public health community about this poorly understood but highly prevalent practice. □

Acknowledgments

We would like to thank Lee Sanderson, PhD, and Emma Frazier, PhD, of the Office of Surveillance and Analysis, CDC, for their help in using these data. In addition, we acknowledge the state BRFSS coordinators, without whose cooperation this work would not have been possible.

Intestinal Parasites among North Carolina Migrant Farmworkers

Stephen D. Ciesielski, PhD, John R. Seed, PhD, Juan C. Ortiz, MSPH, and Jobe Metts, MD

ABSTRACT

Objectives. The public health significance of intestinal parasitism among migrant farmworkers has been poorly defined. We report a three-part study in which we attempted to provide population-based estimates and identify risk factors for infection.

Methods. Parasite prevalence and incidence were estimated from two cross-sectional studies and a longitudinal study. We used questionnaires and clinical measurements such as hematocrits to examine risk factors and health effects.

Results. In the 1987 convenience sample (n = 265), parasite prevalence ranged from 28% among the US born to 86% among the Central American born, with no significant difference between the prevalence of pathogens among US-born (14%) and Mexican-born (24%) subjects ($P = .12$, χ^2 test). High prevalences were also found in the 1988 random sample. An annual incidence of 9.5% (n = 74) was demonstrated in 1988. Symptoms such as abdominal pain were associated with infection, and lower hematocrits were associated with hookworm infection ($P = .02$, t test).

Conclusions. Infection with intestinal parasites appears to be an occupational hazard of farmwork, necessitating improved working and living conditions and greater clinical awareness. (*Am J Public Health.* 1992;82:1258–1262)

Introduction

Migrant farmworkers work and live in substandard hygienic conditions,[1–4] often in areas of the United States formerly hyperendemic for hookworm and other intestinal parasites. Immigrants from developing regions often enter farmwork, increasing the potential for transmission of parasites. Discussions of the health of farmworkers usually cite intestinal parasites as a major problem.[1,4,5] However, previous research has focused on children, a small minority of the population, and made little attempt to quantify transmission and risk factors or to describe associated morbidity.[2,3] We report the results of a three-part study of intestinal parasites among farmworkers in North Carolina, conducted in 1987 and 1988.

Methods

The 1987 prevalence study used a convenience sample of migrant camps in eastern North Carolina, including a representative range of camp condition and size. All individuals living in selected camps were eligible subjects. In 1988 a clustered random sample was obtained by selecting a 10% probability sample from a pooled list of camps. Because of high nonresponse rates, US-born Blacks were excluded from the 1988 sample. Our 1988 longitudinal study included all subjects relocated from the 1987 prevalence study.

After obtaining informed consent, we used pretested, verbally administered questionnaires in English, Spanish, or Haitian Creole to obtain data on demographic, health, and occupational variables. Parents supplied information for children less than 16 years old.

Subjects were given transport kits containing poly-vinyl alcohol and 10% formalin (Trend Scientific, St. Paul, Minn.). After our formalin ethyl-acetate concentration (CON-Trate System, Trend) of the samples, we employed Lugol's iodine and Tri-Chrome stain (Trend) in our microscopic examination. We used Direct Fluorescent Antibody tests (Meridian Diagnostics, Inc., Cincinnati, Ohio) to screen for *Cryptosporidium*, with acid fast dimethyl-sulfoxide stain (Trend) for confirmation. Water from camps in the 1988 prevalence and incidence studies was tested for total and fecal coliforms (membrane filtration method) using standard methods.[6]

Our statistical analysis was performed with SAS and consisted of χ^2 tests, Fisher's Exact Tests, t tests, and logistic regression. The 95% confidence intervals (CI) are not test based.

Results

1987 and 1988 Cross-sectional Studies

In 1987, 265 subjects in 24 camps in three counties participated; 54% of subjects provided one stool sample, 39% provided two, and 7% provided three. Nonresponse was 5% among Haitians, 15%

This paper was submitted to the Journal April 4, 1991, and accepted with revisions March 24, 1992.

among Central Americans, 35% among Mexicans, and 55% among US-born Blacks. The 1988 random sample included 181 subjects from 20 camps in four counties; 47% provided two samples, and 53% one. The 1988 nonresponse was similar to 1987, but higher among Central Americans (50%).

Most subjects in 1988 were young adult males from rural backgrounds with little education (Table 1). Demographics of the 1987 convenience sample were similar, except that US-born Blacks were included. Parasite prevalence was high in both years and usually varied little between years (Table 2). In 1987, 52% of all subjects were positive vs 58% in 1988. Most infections were with pathogens (defined in Table 2). In 1987 hookworm was the most prevalent pathogen among the foreign born, with a prevalence of 58% among Central Americans (28% in 1988) and 20% (24% in 1988) among Haitians (Table 2). The 1988 pathogen prevalence among both Haitians and Central Americans was significantly greater than among Mexicans ($P = .023$, relative risk (RR) = 2.7, 95% CI 1.3, 5.6; and $P = .030$, RR = 2.48, 95% CI 1.1, 5.7, χ^2 tests, respectively). One Central American subject had a *Taenia* infection.

In 1987, parasite prevalence was 28% and pathogen prevalence was 14% among the US born (50% of infected subjects were Hispanic and 50% US-born Blacks). The US-born subjects' prevalence of *Giardia* exceeded that of the Haitian born (RR = 7.2, 95% CI 1.0, 51, χ^2 test) and Mexican born (RR = 3.6, 95% CI .44, 29, χ^2 test); their *H. nana* prevalence exceeded that of the Mexican born; and their prevalence of *E. histolytica* and *E. coli* was comparable to foreign-born subjects. There was no significant difference in pathogen prevalence between the US and Mexican born ($P = .120$, χ^2 test).

In both years of the study, foreign-born subjects' return visits to their countries of origin were not associated with infection ($P > .05$, χ^2 tests). Measures of previous exposure in country of origin (age, sex, educational level, rural upbringing, previous agricultural work) were not associated with infection among foreign-born subjects in 1987 ($P > .05$, logistic regression). Among subjects in the 1988 sample, rural upbringing and previous farmwork were associated with all classes of parasite except protozoa ($P < .05$, logistic regression). Among foreign-born subjects of both years, grouped by birthplace, there were no differences in years of US residence between infected and uninfected subjects ($P = .24$–$.81$, t tests).

TABLE 1—Demographics of Subjects in 1988 Cross-sectional Study of Intestinal Parasites in Migrant Farmworkers

	All Subjects (n)[a]	Haitians (n)[a]	Hispanics (n)[a]
Male, %	80 (181)	74 (50)	83 (129)
Over 16 years of age, %	90 (181)	100 (50)	86 (129)
Mean age	29 (181)	39 (50)	25 (129)
Mean years in farmwork	4.8 (134)	5.5 (48)	3.9 (96)
Mean years in US	4.9 (145)	5.6 (48)	4.6 (97)
Mean exits from US	1.2 (145)	0.5 (48)	1.6 (97)

Previously in agriculture, %	38 (134)	60 (48)	24 (86)

[a]Number of subjects varies because some variables were not applicable to all subjects (particularly children).

In 1987, prevalence of intestinal parasites in Haitian camps ranged from 22 to 70%, in Mexican camps 0 to 60%, and in Black American camps 0 to 30%. This variation was not associated with years in the United States, age, gender, previous risk factors, or condition of camps.

Many subjects reported workplace conditions or behaviors with risk for infection (Table 3), but these variables were not associated with infection ($P > .05$, logistic regression). Among US-born children, day-care attendance was not associated with infection ($P = .574$, χ^2 test), but infection was associated with children accompanying parents to harvest fields ($P = .032$, RR = 2.4, 95% CI 1.3, 4.6, χ^2 test).

Reported symptoms had many significant associations with parasitic infections of different classes (Table 4). Symptoms were consistently associated with pathogenic parasites but not with nonpathogens (not shown).

The mean hematocrit of subjects (in 1988) with hookworm infection was 39.4% and that of the uninfected was 43.0%, a significant difference ($P = .02$, t test). The difference was most pronounced among Hispanic subjects (uninfected = 43.3%, infected = 37.1%, $P = .02$).

1988 Longitudinal Study

In 1988, 74 of 265 subjects (28%) were relocated in 11 camps, without nonresponse. Seven subjects (9.5%) without evidence of infection in 1987 were infected in 1988 with *G. lamblia, T. trichiura,* or *Entamoeba coli.* Latrines rather than flush toilets in camps were associated with incidence ($P = .008$, RR = 13.1, Fisher's Exact Test), as was the presence of coliforms in drinking water ($P = .011$, RR = 7.6, Fisher's Exact Test). Total coliforms were demonstrated in 44% and fecal coliforms in 26% of 27 camps (results published separately[7]).

Discussion

This study provides the first estimates of parasite prevalence among adult farmworkers, the first population-based estimates, and limited data on risk factors for infection. The results indicate that intestinal parasitism is a public health problem among farmworkers. The predominance of hookworm infection—which exceeded that of earlier studies by 6 to 20 times—is especially significant because of its pathogenic potential. However, the results also demonstrate the difficulties in applying standard epidemiologic methods to the study of migrant health. Logistical problems are partly responsible: one example is the more than 30 000 miles driven by field workers in the two years of study.

The estimates of prevalence are substantially higher than previous studies.[2,3] Although prevalence may vary among sub-populations and geographically, a population-based sampling design should provide more valid estimates. However, the majority of subjects were obtained by convenience sampling, and efforts to achieve representativeness can never avoid bias. The often close agreement in prevalence between years may suggest that the 1987 sample is reasonably representative. Nonresponse in field studies of intestinal parasites is always a problem, and the relatively high rate among some groups limits the certainty of these estimates. Nonresponse was lowest among the high-prevalence groups, which would tend to overestimate prevalence. Other

factors (such as often obtaining only one stool sample) tend towards underestimation.

Transmission of parasites in the migrant population is indicated by several results:

1. The parasite prevalence of 28% among US-born subjects in 1987. Although the source of infection cannot be determined with confidence in a cross-sectional study, it is a reasonable assumption that most infections among the US born were acquired in farmwork, especially because most children had lived in this environment their entire lives.
2. The absence of a significant difference between the prevalence of pathogenic parasites among the US and Mexican born in the 1987 sample.
3. The prevalence of several parasite species among the US-born subjects that equaled or exceeded that of the foreign born.
4. The absence of any difference in years of US residence between infected and uninfected subjects. Parasite prevalence among nonfarmworker immigrants to the United

States decreases with increasing years of US residence.[8]

5. The annual incidence rate of 9.5%.

Use of a control group could have demonstrated more conclusively that the prevalence among US-born farmworkers exceeds the nonmigrant population. However, only longitudinal study can prove that infections are acquired in farmwork. Identification of a suitable control group would be difficult; in North Carolina there is no demographically similar group of working adults with such a low socioeconomic status. Future studies should employ one if conducted in Florida or California, where demographics make construction of a control group more feasible.

A cross-sectional design limits assessment of risk factors. Permission to directly inspect workplace conditions was denied; subjects reported conditions for the month prior to study, but working conditions may change weekly or daily. A sample size several times larger than described here would be needed to demonstrate an association between infection and risk factors cross-sectionally. Nevertheless, the potential for transmission is evident in the lack of field sanitation and other workplace conditions. The association between infection and children accompanying parents to the fields indicates occupational risk.

Obstacles to conducting longitudinal study are also substantial, given the transience of farmworkers. The incidence rate of 9.5% reported here is the first attempt to quantify transmission. However, problems include the small sample size (74 subjects) and the possibility of false negatives in 1987. The associations between infections counted as incidence and camp conditions such as latrines and coliforms in drinking water support the classification of these as new infections. However, because all three incident parasites (especially *Trichuris*) can be transmitted via nonwater routes, the importance of water as a means of transmission remains undefined.

The clinical significance of intestinal parasitism among farmworkers has been inconclusively addressed in previous studies. In this study, hematocrits and reported symptoms indicate that parasitism causes morbidity among farmworkers, although many infections may be asymptomatic. Although only one *Taenia* infection was demonstrated, it suggests the possible spread of cysticercosis among farmworkers. The seroprevalence of cysticercosis was 10% in a random sample of NC farmworkers.[9]

Descriptions of the health of farmworkers usually cite intestinal parasites as a paramount problem. Yet no one would maintain that parasitic infections are of greater significance than hypertension, diabetes, or the human immunodeficiency virus. The shock value of parasites is obviously one reason for this emphasis. But it is also true that parasitic infections are a sentinel health event. Their transmission indicates that working and living conditions place workers at risk for a variety of other enteric infectious diseases—both bacterial and viral—transmitted in a similar fashion. Farmworkers have rates of diarrhea 20 times that of the urban poor,[4] and such pathogens must contribute to this disparity.

We conclude that there is good evidence for the transmission of intestinal parasites within the conditions of migrant farmwork, and that infection with parasites is associated with some degree of morbidity. Workplace conditions present clear potential sources of infection. Farmworkers and their families are obviously at greatest risk. However, parasitic ova and cysts remain viable for long periods of time on produce,[10–12] creating some risk for the general public. In 1991 a North Carolina man who lived on a family farm employing migrant farmworkers (from areas endemic for cysticercosis) was diagnosed as having cerebral cysticercosis, a potentially fatal disease.[13] This infection was almost certainly acquired from the farm's employees. On the basis of the results of this study, we make the following recommendations:

- Enforce more strictly the regulations concerning field sanitation and hygiene.
- Replace latrines in migrant camps with flush toilets.
- Improve the surveillance of the microbiologic quality of drinking water in migrant camps.
- Routinely include intestinal parasitism on differential diagnoses of gastrointestinal complaints of all groups of farmworkers, including US-born blacks.
- Routinely screen high-risk patients such as Haitians and Central Americans for intestinal parasites, even when they are presenting other complaints: treatment of asymptomatic individuals can have an important public health function. □

Seventh National Conference on Chronic Disease Prevention and Control

The Centers for Disease Control, the Association of State and Territorial Health Officials, and the Association of State and Territorial Chronic Disease Program Directors will cosponsor the Seventh National Conference on Chronic Disease Prevention and Control, October 21 to 23, 1992, in Salt Lake City, Utah. The conference is open to the public. This year's theme is "Prevention: Can It Be Marketed, Managed, and Make a Difference?"

The conference will emphasize interactions among federal, state, and local health departments, voluntary health agencies, and professional organizations. Presentations will be given in plenary, invited, abstract, poster, and workshop sessions. Topics will include: "Universal Access: Future Implications for Prevention and Public Health"; "Behavioral Research: What Have We Applied?"; "Prevention Effectiveness: Documenting Our Successes"; "The Tobacco Industry's Tactics and Their Implications for Public Health"; "The Family High Risk Program: The Ultimate in Targeted Interventions"; "Clinic-Based Interventions"; "Reaching Children and Adolescents"; "Smoking and Health"; "Nutrition and Chronic Disease Prevention"; "Reaching the Underserved"; "Using the Latest in Computer Software for Public Health"; "Enlisting Minority Health Organizations in Chronic Disease Advocacy"; and "International Chronic Disease Prevention and Control."

Restricted Activity Days among Older Adults

ABSTRACT

Objectives. The number of restricted activity days experienced by an individual in the course of a year is an important measure of functional well-being, particularly for older adults. We sought to determine multivariate associations between restricted activity days and various health conditions.

Methods. We used data from the 1984 Supplement on Aging of the National Health Interview Survey to estimate the relationship between restricted activity days and age, gender, and the presence or absence of selected chronic conditions and falls for all noninstitutionalized people aged 65 years and over. Chronic conditions and falls accounted for most of the variance in the model.

Results. Of an annual average of 31 restricted activity days, 6 days were associated with falls; 4 days with heart disease; 4 days with arthritis and rheumatism; 2 days each with high blood pressure, cerebrovascular disease, and visual impairment; and 1 day each with atherosclerosis, diabetes, major malignancies, and osteoporosis.

Conclusions. These results can be used in estimating the potential impact of health promotion programs on the health status of noninstitutionalized older adults. (*Am J Public Health.* 1992;82:1263–1267)

Introduction

A restricted activity day, as defined in the National Health Interview Survey, is a day in which an individual spends over half of the day in bed, home from work or school, or cutting down on usual activities because of illness or injury.[1] The number of restricted activity days experienced by an individual in a year is an important measure of functional status and well-being,[2] assessed in the National Health Interview Survey for many years.[3] One of the surgeon general's two major goals for older adults, as stated a decade ago in *Healthy People,*[4] was to improve the health and quality of life by reducing the average annual number of days of restricted activity due to acute and chronic conditions by 20%, to fewer than 30 days per year for people 65 years of age and older. (A change in the order and wording of the 1982 National Health Interview Survey questions regarding restricted activity days resulted in about 20% fewer reported restricted activity days per person.[3,5] Thus, if we adjust for the questionnaire change, the goal of 30 days [as written before 1982] is probably equivalent to 24 days, as measured by post-1982 questionnaires [30 days less 20%].)

Because the meaning of "restricted activity" depends in part on what activities are usual for an individual and on his or her subjective judgment about degree of limitation due to injury or illness, the restricted activity day is thought by some to be "less than an ideal indicator of the health status of older adults."[6] However, Scholes et al. recently demonstrated that restricted activity days correlate well with important physical health status measures.[7]

The purpose of this paper is to estimate the relationship between restricted activity and the presence or absence of major chronic conditions, falls, increasing age, and gender. Several published studies have shown bivariate associations between the number of restricted activity days per person per year and various health conditions.[1,8,9] In addition, Verbrugge et al. investigated multivariate associations (comorbidity) between several chronic conditions and physical well-being as measured by the number of activities of daily living performed with difficulty.[10] We present multivariate analyses of the association of health conditions with restricted activity days. Such information may be useful in identifying risk factors for disability, assessing priorities for prevention among older adults, and predicting the potential population impact of health promotion interventions.

Methods

Data and Selection of Variables

dom sample of adults 55 years of age or older from the noninstitutionalized US population during 1984.[11,12] We have examined the findings for the 11 497 subjects 65 years of age or older. Information on a variety of health-related topics was obtained for each individual, including the number of restricted activity days experienced in the 2-week period preceding the interview and the presence or absence of selected health conditions from a uniform list of 43 conditions.[12] The Supplement on Aging questionnaire differs from the standard National Health Interview Survey practice that randomly assigns only one of six different lists of conditions to each subject. The Supplement on Aging data also were used by Verbrugge et al. in their research on comorbidity.[10] The 14-day data were converted to annual rates.

In the interest of parsimony, clinically similar chronic conditions were combined prior to development of the multivariate models; conditions associated with less than 5% of the total annual restricted activity days were excluded. Age was recorded as a binary variable (0 = age 65 through 74, 1 = age 75 or over). Table 1 shows the average annual restricted activity days overall (31.4 days per year) for people who reported each health condition analyzed. For example, people with visual impairment averaged 60.2 restricted activity days per year and accounted for 21.6% of all annual restricted activity days.

These prevalence rates are based on self-reports by noninstitutionalized respondents. Alzheimer's disease is an obvious example of underreporting. Other weaknesses inherent in the Supplement on Aging data set that limit its ability to provide information on components of morbidity among institutionalized adults have been discussed extensively by Verbrugge et al. However, these authors concluded that if the scope of the research is to determine how disabling certain reported chronic conditions are for noninstitutionalized community residents, then the data set is appropriate and advantageous because of its size and national span.[10]

The National Center for Health Statistics has compared interview data with medical records data from a population in the Kaiser Foundation Health Plan of Southern California and reported good agreement, especially for cardiovascular disease.[13] Unfortunately, several additional important health conditions were not adequately addressed in the Supplement on Aging questionnaire and could not be included in the model, including chronic lung disease, back problems, chronic gastrointestinal disorders, paralysis, other problems with lower extremities, other musculoskeletal disorders, and depression.

Preliminary Analysis

Because the National Health Interview Survey is a stratified, clustered random sample and not a simple random sample, the analyses must take into account the survey design effect.[12] We performed preliminary analyses using ordinary weighted least squares and then estimated the final models (including variances and *P* values) using the stratified, clustered sample procedures found in PC-CARP software.[14]

We also analyzed bed disability days but preferred restricted activity days both because of the use of this variable by the surgeon general[4] and because our analyses of both variables showed restricted activity days (after correction for the 1982 National Center for Health Statistics/National Health Interview Survey questionnaire change) to be a more stable dependent variable than bed disability days, as in the analyses of Scholes et al.[7]

Final Analysis

With the number of restricted activity days experienced in a 2-week period as the dependent variable, the independent variables selected for analysis included age, sex, and presence or absence of the 17 selected health conditions during the time periods specified in Table 1. We performed bivariate regression of restricted activity days on each independent variable in order to estimate zero-order associations with restricted activity days. We performed multiple stepwise linear regression for a model in which all independent main effects were forced to enter, and then used an entry *P* value of .05 and an exit *P* value of .10 in order to arrive at a parsimonious model containing main effects. Leaving these main effects in, we used the same stepwise regression methods to search for significant interactions between each health condition and either age or sex and between age and sex. Leaving these main effects and significant interactions in, we used the same stepwise procedures to examine any significant two-way interactions among the set of 59 health condition interactions that were associated with at least 5% of the total annual restricted activity days experienced (same lower bound as in the initial selection of independent variables). Each of the above models was confirmed in PC-CARP.

Results

The relationships between main effects (independent variables) and restricted activity days are summarized in Table 2. Since the 2-week averages result from properly weighted observations taken from all quarters of the year, this conversion to annual rates should produce properly weighted averages for all seasons.[11] The second column in Table 2 contains the regression coefficients for each variable when that was the only variable in the model. This value estimates the differ-

ence between populations with the specified condition and populations without. For age, the condition is being 75 years old or older; for sex, female. In this column, cerebrovascular disease shows the greatest association with restricted activity (55.9 days).

The third column in Table 2 shows coefficients for the final main effects model. A zero without any decimals indicates that the variable was left out of the model by the model selection criteria and its effect was thus taken to be zero. In this column, the effect of cerebrovascular disease is still the highest (35.2 days), but the magnitude of the coefficient is lower, because some of the apparent effect of cerebrovascular disease can be accounted for by the presence of other conditions. In fact, all coefficients in the final main effects model are smaller than their zero-order counterparts, indicating that many of these conditions are correlated.

The fourth column of Table 2 presents estimates with an interpretation similar to those of the third column, except that all variables were forced to enter into the model. By comparing this column with the final main effects model (third column), the stability of the coefficients of variables left in the final main effects model can be verified. The variables left out of the final main effects model do not have a large influence on the variables that were left in.

When the age by sex interaction and all interactions between each health condition and either age or sex were examined as possible additions to the final main effects model, none was statistically significant. When all 59 two-way interactions among selected health conditions were examined in the presence of the final main effects model, only four remained significant at the .05 level in PC-CARP. The resulting model will hereafter be referred to as the final interaction model. The estimated main effect and interaction coefficients for this model are given in the fifth column of Table 2, along with the model R^2 and overall P value. Confidence intervals for the parameters of this model are not given because it is difficult to interpret confidence intervals in the presence of interactions.

Main effect coefficients that differ between the final main effects model and the final interaction model are part of interactions (e.g., "falls by arthritis and rheumatism"). In addition, the baseline estimate increases in the interaction model. Overlap between main effects cannot be accounted for in a main effects model, resulting in a low estimate of the effect of conditions not included in the model. The actual average from the data for people with none of the 17 selected conditions is 10.5 restricted activity days per year. The estimated baseline level of 8.4 in the final interaction model is closer than the estimate from the final main effects model (6.2).

TABLE 2—Estimated Model Coefficients for Four Different Models Predicting the Annual Number of Restricted Activity Days

Final Condition (Independent Variable)	Regression Coefficients (In Days per Annum) Predicted by Four Models: Zero Order	All Main Effects (95% Confidence Interval)	Effects Forced in	Final Interaction
Visual impairment	32.5	16.3 (9.4, 23.2)	15.7	16.6
Cataracts	11.2	0 ...	0.0[a]	0
Glaucoma	14.3	0 ...	5.9[a]	0
Hearing impairment	7.4	0 ...	−1.4[a]	0
Tinnitis	9.7	0 ...	1.8[a]	0
Falls	38.6	27.4 (23.1, 31.8)	27.3	19.7
Osteoporosis	41.8	27.1 (16.2, 37.9)	27.2	26.8
Hip fracture	24.7	13.0 (1.4, 24.6)	12.5	13.3
Atherosclerosis	36.6	13.6 (5.6, 21.7)	13.2	7.9
High blood pressure	15.3	4.5 (1.4, 7.6)	4.5	3.2

Note. The coefficient values for each model can be interpreted as the additional number of days experienced in association with the presence of the corresponding condition (n = 11 497 persons 65 years of age and older).
[a]Not significant at the .05 level.

Using the final main effects model, we estimated the average number of restricted activity days per year for persons 65 years old or older that may be directly associated with each condition. These estimates (Table 3) were calculated by multiplying the model coefficient for the condition by the prevalence of the condition per individual, that is, column 3 = column 3 in Table 2 × (column 2 in Table 3/1000). Column 4 in Table 3, in which the resulting measure is expressed as a percentage of the overall average number of restricted activity days, is analogous to the "etiologic fraction" sometimes used as a measure of effect in epidemiologic studies.[15] It is interesting to note that whereas cerebrovascular disease has the largest model coefficient, both falls and arthritis, when multiplied by prevalence, become larger contributors to total annual restricted activity days.

Values for the final interaction model were calculated in the same manner. For those main effects that were part of an interaction, the corresponding days and percentage of days for the associated interaction were added to the main effect values (columns 5 and 6, Table 3). For example, the average annual days directly associated with falls was calculated by multiplying its prevalence by its coefficient [(203.7/1000) × 19.7 = 4.0] and adding this product to the prevalence of the arthritis and rheumatism combination multiplied by its coefficient {4.0 + [(123.7/1000) × 13.6] = 5.7}.

TABLE 3—Estimates of Average Annual Restricted Activity Days per Person Directly Associated with Conditions Significant in the Final Main Effects Model and in the Final Interaction Model

Condition	Condition Prevalence per 1000	Final Main Effects Model: Annual Days Directly Associated with Condition	Final Main Effects Model: Days Directly Associated with Condition, %	Final Interaction Model: Annual Days Directly Associated with Condition	Final Interaction Model: Days Directly Associated with Condition, %

Overall average	...	31.4	100.0	31.4	100.0
Baseline level	1000.0	6.2	19.6	8.4	26.9

Some of the days directly associated with a condition are counted twice. For example, the days directly associated with the falls by arthritis and rheumatism interaction are added to both the falls main effect and the arthritis and rheumatism main effect. The overlap resulting from each interaction (the value counted twice) is given in the last four lines of columns 5 and 6 in Table 3. Summing the percentages in the last column for the baseline level and main effects and then subtracting the overlap values from the interactions will result in 100% (within rounding error).

Discussion

Neither age, sex, nor any interaction with age or sex was significantly associated with restricted activity days in the presence of self-reported conditions. Verbrugge et al. obtained similar results from their regression analyses.[10] This finding supports the concept that the functional decline commonly associated with age is not a direct consequence of advancing age per se.[16,17] Instead, functional impairment may be viewed as resulting from certain medical conditions associated with age, and against which preventive interventions may be aimed.

These results also may be helpful in prioritizing health conditions for interventions: the larger the number of restricted activity days attributable to a given health condition, the greater the potential overall impact of preventing that condition.

Subject to certain assumptions discussed below, the estimates from the final interaction model (Table 3) can be used to estimate the potential population impact of specific health interventions for noninstitutionalized people 65 years of age or older. For example, suppose we have an intervention against falls that may reduce by 50% the total number of people experiencing a fall in 1 year. From Table 3, we know that falls are associated with about 18% of all restricted activity days experienced in the United States; we would, therefore, estimate that the proposed intervention could reduce the total number of restricted activity days by about 9%.

The effects of interventions with multiple benefits, such as those against smoking and/or high blood pressure, could be estimated similarly by determining the interrelationships between the various risk factors and health conditions involved and then multiplying the resulting reductions in health condition prevalences by the direct effect estimates found in Table 3. Care must be taken to ensure that the estimated overlap is subtracted. For example, a 50% reduction in both falls and arthritis and rheumatism would result in an estimate of (50% × 18.1%) + (50% × 13.0%) − (50% × 5.4%) = 12.9% reduction, where 5.4% is the overlap in percentage of days associated with the falls by arthritis and rheumatism interaction. The resulting value could be used as an estimate of the potential effectiveness of the given intervention in reducing restricted activity for noninstitutionalized populations 65 years of age and older.

The R^2 values at the bottom of Table 2 indicate that only about 8% of the variability in restricted activity days was explained by the conditions in the models. This is not surprising, since people have restricted activity days for many other reasons than falls and chronic conditions. Thus, this model would not be appropriate for predicting the number of restricted activity days for an individual. However, it provides some useful guides for patient groups, as can be seen in the confidence intervals in Table 2 for each parameter in the final main effects model. The effects of chronic conditions on restricted activity days are statistically significant, large, and consistent with clinical impressions. For example, the impact of arthritis on restricted activity days for people who suffer from arthritis is smaller than the impact of cerebrovascular disease for people who have that disease, although both conditions are significantly associated with restricted activity days and arthritis is much more prevalent. There is a larger potential for reduction in restricted activity days for the cerebrovascular disease group.

We cannot be certain that any given condition (falls, for example) *caused* the restricted activity days with which it was associated in this data set, or, more important, that preventing half of all falls—if we could—would reduce the average number of restricted activity days for the entire older adult population by 2.8 days per year (Table 3). The occurrence of a fall may reflect underlying frailty that itself increases the number of restricted activity days by other mechanisms. In addition, if other significant variables, such as severity or duration, were included in the model, the coefficient for falls from the final main effects model might drop below 27.4 days per person per year.

Our analysis was limited to conditions prevalent in noninstitutionalized persons and about which questions were asked in the National Health Interview Survey Supplement on Aging. Omission

of other important conditions, such as respiratory disease, depression, alcoholism, or Alzheimer's disease, could have either or both of two effects. First, if an omitted condition is associated with another condition included on our list, then we may incorrectly ascribe an effect to an included condition, when in fact part of that effect is due to the omitted condition(s) with which it is associated. Second, absence of data on important omitted conditions may show up as a low R^2 value: part of the unexplained variability in restricted activity days may have been explainable with additional predictor variables. We also do not know how direct the association is between a chronic condition and the number of restricted activity days; perhaps some chronic conditions are associated with an increase in acute conditions that, in turn, accounts for additional days of restricted activity. Nevertheless, our multivariate model represents a considerable improvement over bivariate analyses, as illustrated by the difference between the estimates of 27.4 days associated with falls in Table 2 and 62.1 days in Table 1.

Although additional data and more research are needed to increase its precision and broaden its applicability, the model presented in this paper should be useful in designing and evaluating health promotion interventions for older adults. □

Predictors of Smoking Cessation and Relapse in Older Adults

Marcel E. Salive, MD, MPH, Joan Cornoni-Huntley, PhD, Andrea Z. LaCroix, PhD, Adrian M. Ostfeld, MD, Robert B. Wallace, MD, and Charles H. Hennekens, MD, DrPH

ABSTRACT

We examined longitudinal changes in smoking behavior among older adults in three community cohorts of the Established Populations for Epidemiologic Studies of the Elderly. Smoking prevalence declined from 15% at baseline to 9% during 6 years of follow-up. Annual smoking cessation and relapse rates were 10% and less than 1%, respectively. Interval diagnosis of myocardial infarction, stroke, or cancer increased subsequent smoking cessation but not relapse. Although smoking cessation around diagnosis is increased, primary prevention could yield greater benefits. (*Am J Public Health.* 1992; 82:1268–1271)

Introduction

Cigarette smoking is the leading cause of premature mortality among older persons, primarily due to cancer and cardiovascular disease.[1–4] Smoking cessation has health benefits, largely cardiovascular, before and after age 65 years.[3–6] Although 4.5 million older adults continue to smoke regularly, 10 million have quit.[7] Older smokers are more likely to quit than younger smokers,[8–12] possibly as a result of disease events, severity of illness, or hospitalization.[6,7,12–13]

Previous reports from the Established Populations for the Epidemiologic Studies of the Elderly (EPESE) compared current, former, and never smokers at baseline[14] and their 5-year mortality during follow-up.[4] This study examined smoking cessation and relapse during follow-up and their predictors, particularly chronic disease events, in three community cohorts. We examined heart attack, stroke, and cancer because they are associated with smoking and increase with age.

Methods

The data were taken from the East Boston, New Haven, and Iowa and Washington counties EPESE communities, which enrolled approximately 10 300 participants 65 years of age or older beginning in 1981. Details of the methods have been published.[4,14–16] Trained interviewers conducted baseline household surveys and six annual follow-up interviews (telephone and in person) that included information on demographics, medical history, and health-related behaviors. Of eligible community residents, 80% to 84% completed initial interviews, and annual follow-up rates were above 95% in each community.

This analysis followed baseline current and former cigarette smokers to determine smoking status 3 and 6 years later. Smoking status, determined by two questions ("Do you smoke cigarettes [regularly] now?" and "On the average, how many cigarettes per day do you [usually] smoke?"), was unavailable in less than 1% of completed in-home interviews. Cessation and relapse were defined as a change in smoking status at follow-up among current and former smokers, respectively. Additional baseline questions included prior smoking ("Did you ever smoke cigarettes [regularly]?"), and age of initiation or cessation, if applicable. Number of years of smoking was computed.

All interviews included questions about the diagnosis of myocardial infarction, stroke, and cancer by a physician (or,

in East Boston, another health care provider). Exertional chest and leg pain were assessed at baseline.[17]

Cessation and relapse rates were age adjusted by the direct method using the combined baseline population. The communities were grouped to examine factors associated with smoking cessation and relapse using categorical methods. Logistic regression models[18] used either smoking cessation or relapse as the dependent variable in multivariate analysis to adjust for demographics and smoking intensity.

Results

Smoking prevalence declined from 15% at baseline to 12% and 9% at years 3 and 6, respectively. After 3 years, 357 (28%) of 1259 baseline smokers had quit. By 6 years, the cessation rate increased to 46%; 433 of 944 baseline smokers had quit. Age-adjusted cessation and relapse rates differed little by gender and site (Table 1). Eighty-seven percent of surviving 3-year quitters remained nonsmokers at the final follow-up.

Smoking cessation in 3 years (Table 2) was independently and significantly ($P < .05$) associated with older age; never having been married; smoking fewer cigarettes per day; fewer years of smoking; no history of myocardial infarction, stroke, cancer, or report of angina or intermittent claudication at baseline; and interval diagnosis of myocardial infarction, stroke, or cancer. Smokers in Iowa were more likely to quit than those in New Haven (relative odds = 1.5, 95% CI = 1.0, 2.3), adjusting for variables in Table 2. Smoking cessation in 6 years was independently and significantly associated with non-Black race, smoking fewer cigarettes per day, and interval diagnosis of myocardial infarction, stroke, or cancer (Table 3).

Among former smokers, the relapse rate was 3%: 68 of 2050 baseline former smokers relapsed by 3 years and 44 of 1515 relapsed by 6 years, respectively. Three-year smoking relapse was predicted by younger age, heavier smoking history, and quitting smoking later in life (Table 4). Two fifths of former smokers who relapsed by year 3 had quit again by year 6, thus yielding too few persons for multivariate analysis.

Discussion

Older adults in these community-based samples had annual smoking cessation and relapse rates of 10% and less than 1%, respectively. Interval diagnosis of myocardial infarction, stroke, or cancer was associated with smoking cessation but not relapse. The oldest old were more likely to quit smoking and less likely to relapse than those 65 to 69 years of age. The association of age and intensity of smoking with quitting and relapse is similar to that in younger populations,[7,9,12] as is lower cessation among Blacks.[12] Our sample included an adequate number of smokers through age 84 but few at older ages as a result of lower smoking prevalence[14] and high mortality.[1,4,19]

Several limitations of the data merit consideration. We lacked data on the number of quit attempts, the method of

cessation, and the validity of self-reported smoking status. Self-reported smoking status is usually valid, and many adults successfully quit on their own.[5,10,20] The dates of quitting and disease diagnosis are unknown in some cases. Dynamic patterns were not accounted for because we had limited information about earlier nonsmoking intervals and the length of cessation afterward. The use of baseline and follow-up smoking information misclassified a few quitters but did not affect the significant predictors or our conclusions.

Methodological differences limit comparison of this study with prior work. Prior surveys were cross-sectional[2,5,7,8,10,19,21] or defined cessation differently.[7,10–12] Period differences in cessation rates have been reported.[22] Nevertheless, in younger populations only 33% to 40% quit smoking in a decade.[9,12]

We found, as suggested in middle age,[6,7,12–13] that older adults diagnosed with chronic disease have twofold higher odds of smoking cessation. About 25% of the quitters had a diagnosis of myocardial infarction, stroke, or cancer during the follow-up. The majority who quit do so before or without the onset of these smoking-related illnesses, related in part to demographics, smoking intensity, and possibly to unmeasured factors such as attitudes or other smoking-related chronic conditions or symptoms. Prevalent disease in a baseline smoker, which was inversely related to cessation, may be most common among "hard-core" smokers who did not quit despite their illness. Analysis by duration of illness was not possible.

These findings have important clinical implications for health professionals caring for older smokers. While patients may be highly amenable to smoking cessation around the time of diagnosis of smoking-related illnesses such as atherosclerosis or cancer, primary prevention efforts would have a far greater impact. We join the call for improved cessation initiatives by physicians and other health professionals.[23–25] Given the aging of the US population, which includes younger cohorts with higher smoking prevalence,[19,21] concerted attention to smoking cessation is needed at all ages, including the elderly. □

Acknowledgments

The Tobacco Institute's "It's the Law" Campaign: Has It Halted Illegal Sales of Tobacco to Children?

Joseph R. DiFranza, MD, and Linda J. Brown

ABSTRACT

A survey of tobacco retailers was conducted to evaluate the efficacy of the Tobacco Institute's "It's the Law" program, which has the goal of eliminating the illegal sale of tobacco to minors. Only 4.5% (7) of the 156 retailers surveyed were participating in the "It's the Law" program. Eighty-six percent of the retailers who were participating in the program were willing to illegally sell cigarettes to children, compared with 88% (131/149) of the retailers who were not participating. (*Am J Public Health.* 1992;82:1271–1273)

Introduction

Nationwide, three out of four tobacco retailers illegally sell tobacco to children.[1,2] Consequently, the tobacco industry has been criticized for profiting from the use of a distribution system that results in the illegal sale of $1.5 billion of its products to children each year.[3,4] The easy access to tobacco provided by this distribution system has been identified as an important preventable factor in adolescent tobacco use.[5]

In an attempt to reduce children's access to tobacco, a number of communities have solicited voluntary merchant compliance with laws prohibiting the sale of tobacco to minors.[6–9] Unfortunately, despite

Editor's Note. See related editorial by Giovino et al. (p 1203) in this issue.

a heavy investment of resources, illegal sales have continued to be widespread.[7–9]

By contrast, Woodridge, Ill, has shown that 100% compliance can be achieved quickly and inexpensively with a simple program of compliance checks conducted with the assistance of underage buyers.[5] Most remarkably, the decreased access resulting from active enforcement produced a 50% decline in tobacco use, and a 69% decline in daily tobacco use, among junior high students in Woodridge.[5]

Faced with the national proliferation of effective local legislation concerning the sale of tobacco to minors, the Tobacco Institute on December 11, 1990, announced that it would "help curb youth access to cigarettes through aggressive work with the retail community and by supporting new state laws".[10] Without exception, the new state laws supported by the Tobacco Institute serve to preempt and overturn effective local efforts to control the sale of tobacco to children.[11] For example, a tobacco industry–sponsored bill in Massachusetts would have made it illegal for police to conduct Woodridge-style compliance checks.

The Tobacco Institute's "It's the Law" campaign is marketed as an attempt to "help retailers observe and enforce state laws prohibiting tobacco sales to youth" through the distribution of signs, decals, buttons, employee certification brochures, and other literature.[10]

To determine whether tobacco industry self-regulation is a useful alternative to active enforcement of the law, we sought to test the effectiveness of the "It's the Law" campaign 7 months after its launch.

Methods

Subjects

The subjects for this study were 156 tobacco retailers located by the survey team while driving in central Massachusetts. Retailers located in communities with active enforcement of tobacco access laws were excluded from the study. We had no prior knowledge as to whether retailers participated in the "It's the Law" program or whether they sold tobacco to children.

Procedure

To evaluate merchant compliance with the state law, which prohibits the sale of tobacco to minors under 18 years of age and which requires the posting of warning signs to that effect, we had five underage buyers (aged 13 to 16 years, both male and female) make sham purchases. The prospective buyer would ask the sales clerk for cigarettes, but when the cigarettes were placed on the counter and payment was requested the buyer indicated that he or she did not have enough money and left the premises. With cigarette machines, the underage buyer inserted the correct amount of money and, if he or she had not been stopped at that point, pulled the coin return instead of selecting cigarettes. Buyers were truthful about their age if asked, and made no attempt to appear older. Each establishment was inspected to determine whether it had posted Tobacco Institute "It's the Law" signs or the state-mandated signs. The survey was completed over a 3-week period in the summer of 1991.

Results

The areas surveyed were urban and suburban. Most of the outlets were pharmacies, but convenience stores, gas stations, supermarkets, liquor stores, restaurants, hotels, and a pub were also represented. Eight locations sold cigarettes from vending machines.

Only 4.5% (7) of the 156 retailers surveyed were participating in the Tobacco Institute's "It's the Law" program. Six of the seven participating retailers (86%) were willing to illegally sell cigarettes to children; 88% (131/149) of the retailers who were not participating in the program were willing to sell cigarettes to children. State-mandated warning signs were displayed by 61 retailers, of whom 49 (80%) were willing to illegally sell tobacco to children.

Discussion

We found that the Tobacco Institute's "It's the Law" voluntary compliance program has failed to stop the illegal sale of tobacco products to children. Merchant participation in the program is extremely low, and even participating merchants illegally sell tobacco to children. The participating merchants we interviewed had received their "It's the Law" kits unsolicited, through the mail. By February 1992, the Tobacco Institute claimed to have distributed materials to "thousands of retail outlets across the country" (letter from the Tobacco Institute to Massachusetts Governor William Weld, February 4, 1992).

Health officials should not be deceived by the presence of "It's the Law" signs into thinking that tobacco merchants are complying with the law. Since the industry's attempt at self-regulation has been completely ineffective at reducing children's access to tobacco, the active enforcement of tobacco access laws by health officials is a necessity.

Industry critics have questioned the true motivation behind the "It's the Law" campaign.[12,13] "It's the Law" signs depict a hand brandishing a cigarette and the caption "It's the law/You must be 18 to buy tobacco products." The caption is deceptive, in that in the vast majority of states it is not illegal for minors to purchase tobacco; rather, it is illegal for merchants to sell it to them.[1] Misinformed parents may be afraid to complain about a merchant who is selling tobacco to their children if they mistakenly believe that it is their child who has broken the law.[12] Some observers believe these signs are designed to appeal to teens by presenting tobacco as a forbidden fruit.[12]

The Tobacco Institute has stated that it may spend $10 million on the "It's the Law" campaign over a period of 5 years. However, when we consider that over that 5-year period the tobacco companies will receive over $1 billion in illegal profits from the sale of tobacco to children, we must seriously question the sincerity of their concern.[3]

Active enforcement of tobacco access laws through the use of underage buyers has proved to be a very simple and effective method for decreasing tobacco use among children. The enforcement of these laws is the responsibility of the health community and should not be left to the tobacco industry. □

PHLIS: An Electronic System for Reporting Public Health Data from Remote Sites

Nancy Hargrett Bean, PhD, Stanley Morris Martin, MS, and Henry Bradford, Jr, PhD

ABSTRACT

Disease surveillance conducted by the Centers for Disease Control (CDC) in conjunction with state health departments provides databases of information to public health workers. These databases' utility is limited by the lag time from occurrence of disease events until records are available for analysis. We developed the Public Health Laboratory Information System (PHLIS), a PC-based electronic reporting system for entering, editing, and analyzing data locally and for transmitting data electronically to other state or federal offices. Advantages of PHLIS include reduction in paper handling, decrease in lag time between disease incident and availability of information for analysis, ability to rapidly examine data for clusters of disease, downloadable summary tables, data editing at site of input, data analysis capability, increased interaction among participants, and current data for responses to inquiries. PHLIS is available without cost and is transportable to other agencies, states, or countries. (*Am J Public Health.* 1992;82: 1273–1276)

Introduction

Disease surveillance conducted by the Centers for Disease Control (CDC) with state health departments provides databases that record disease information and data for special studies. These databases provide information to public health workers throughout the United States and other countries. While demand for data is great, utility is limited by the lag time from disease onset until the record is available for analysis. A personal computer–based reporting system was needed for local, county, or state organizations to enter, edit, and analyze data at their own sites and transmit data electronically to other state and federal offices. Although systems exist to address the needs of a single program, a broader system that could be installed in any site (including international), incorporate the needs of divergent organizations, and handle multiple data types was essential. Therefore, we developed the Public Health Laboratory Information System (PHLIS), a flexible system that captures any type of information (e.g., epidemiologic, laboratory, special studies, surveys) from multiple sources (e.g., hospitals, laboratories, state or county offices) and accommodates data transmission regardless of dissimilarities between computer hardware and software at sending and receiving sites.

Several innovative features were designed into PHLIS, for example, a modular approach. Each CDC program responsible for data collection designs and controls each module (a data set containing records concerning a specific pathogen, survey, special study, etc.) in conjunction with state programs. Modules are independent; each can have a unique design (e.g., data entry screen, frequency of data transmission, destination hardware to receive data [personal computer, mainframe, local network, etc.], additional module functions, and analysis and dispersal of data). A decision to change a module does not affect other modules and is limited only by available resources within a program.

Of these features, control and analysis of data are critical. The input of expertise at CDC is maximized by having all programs evaluate and disseminate their data to constituents. This is in contrast to systems that collect, maintain, and evaluate data from multiple sources in one central location. Since CDC collects diverse data for many purposes, it is difficult for any single organization to maintain expertise in all areas.

Nancy Hargrett Bean and Stanley Morris Martin are with the Biostatistics and Information Management Branch, Division of Bacterial and Mycotic Diseases, Center for Infectious Diseases, Atlanta, Ga. Henry Bradford, Jr, is with the Louisiana Public Health Laboratory, New Orleans.

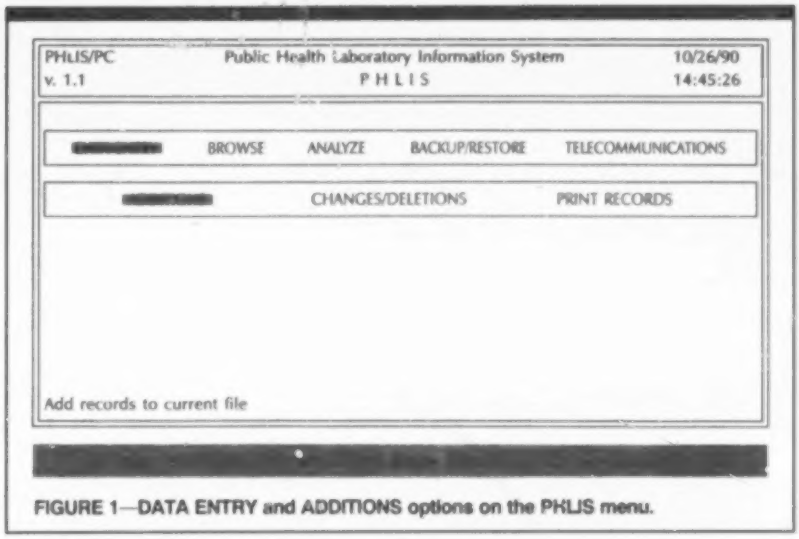

FIGURE 1—DATA ENTRY and ADDITIONS options on the PHLIS menu.

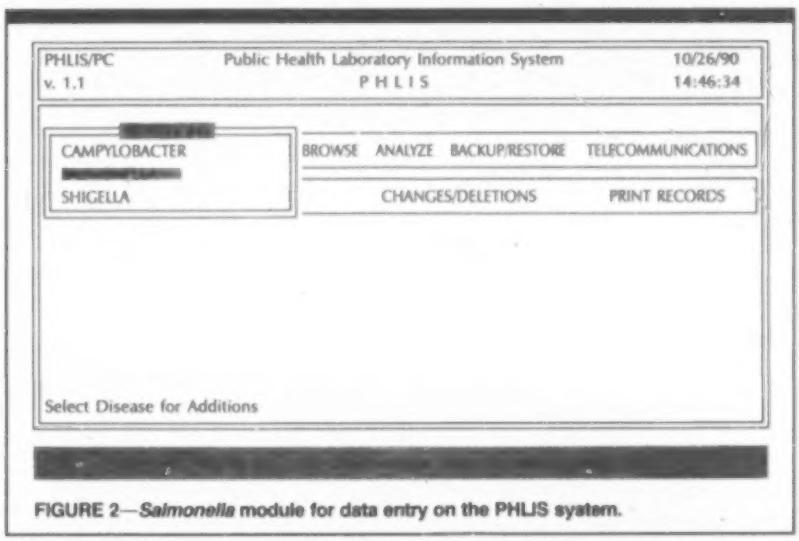

FIGURE 2—*Salmonella* module for data entry on the PHLIS system.

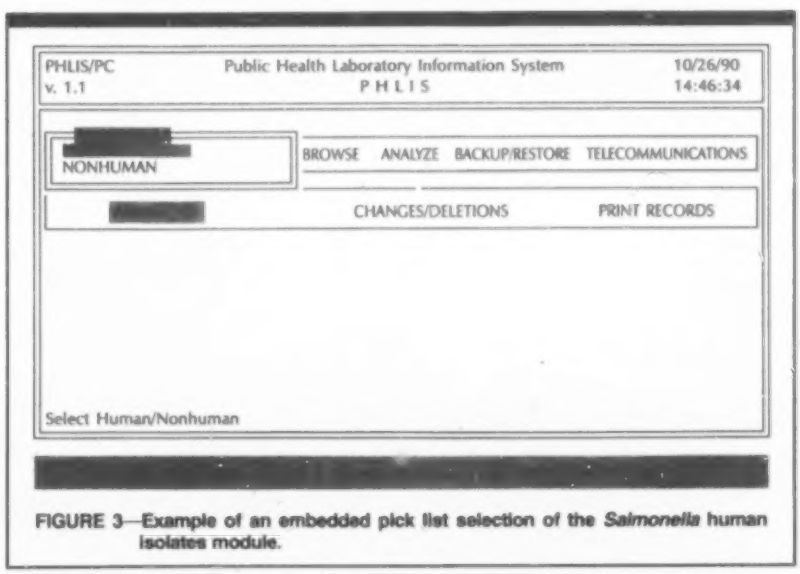

FIGURE 3—Example of an embedded pick list selection of the *Salmonella* human isolates module.

Methods

The Division of Bacterial and Mycotic Diseases, CDC, the Association of State and Territorial Public Health Laboratory Directors, and medical epidemiologists determined which features should be included to meet the needs of potential users. Seven states (Louisiana, New Mexico, Connecticut, Tennessee, Colorado, Delaware, and Maryland) implemented PHLIS using the *Salmonella* surveillance[1] system as the pilot module. Pilot state officials installed and implemented PHLIS with only telephone consultations; no visits to sites by CDC were necessary, and state officials did not travel to CDC for training.

Results

Designed for easy installation and operation, PHLIS requires only a personal computer with DOS[2] 3.0 or higher, a hard disk, at least 512 kilobytes of memory, and a modem. Software for menus provides explicit prompts throughout the system, making PHLIS completely menu driven. PROCOMM PLUS[3] telecommunications software was purchased for participating states. The programs were written using Clipper[4] and Epi Info.[5]

To enter data onto PHLIS select DATA ENTRY, ADDITIONS (Figure 1), and the module (e.g., SALMONELLA). Multiple embedded pick lists are available (e.g., after selection of SALMONELLA [Figure 2], an additional list offers human and nonhuman options [Figure 3]). If *Salmonella* human isolates are selected, the data entry screen for *Salmonella* human isolates appears (Figure 4).

During data entry, the system inhibits input when an error occurs. For example, the serotype is checked for spelling against a list of 1780 serotypes provided in the *Salmonella* module. Other edit features such as range checks and conditional jumps are included.

As a new record is entered, PHLIS assigns a permanent identification number and writes the record to a master file. Transaction files are records not yet sent to other sites, including changes, deletions, and additions. PHLIS recognizes which records have been sent to other sites so that users are not burdened with record tracking. PHLIS adds FIPS county and state codes onto each record as it is entered onto the system.

To change a record, select DATA ENTRY, CHANGES/DELETIONS, a module, and a descriptor (e.g., name). The selected record appears and the user

makes corrections, which are applied to the master file. Corrections and deletions are sent to all receiving sites, including CDC. The BROWSE option provides a way to view but not modify data.

Analysis functions are provided by selecting ANALYZE (Figure 5), a procedure (e.g., LIST VARIABLES), and a module. A listing of module-specific variable names is displayed (Figure 6), eliminating the need to remember variable names. Users are prompted at all steps, enabling novices to perform simple analyses. All Epi Info analysis options are available by selecting OTHER EPI ANALYSIS.

When BACKUP is selected, PHLIS calculates the number of diskettes necessary and allows the user to format additional diskettes. Archived data can be restored by selecting RESTORE, choosing a module, and inserting the archive diskette.

A pyramid structure of data transmission can be developed within states. For example, data initiating locally could be sent to a county or state office and finally to CDC. Alternatively, data can be simultaneously transmitted to state offices and CDC. States retain control over established procedures for data flow, evaluation, and release. The number of participants in a state is not limited, and multiple sites can upload data concurrently.

PHLIS provides several formats for sending data to other sites by specifying the file type (Epi Info, dBASE,[6] ASCII) to be written. Furthermore, if states currently have other types of data systems (e.g., Paradox or VAX), files (ASCII, Epi Info, or dBASE) may be imported into PHLIS in a prescribed format. For example, PHLIS is currently receiving data from two states with VAX systems. Therefore, PHLIS data can be accessed by other software and can incorporate data from other systems.

Data are received via a personal computer dedicated to communications. Selecting SEND TO CDC (Figure 7) and a module causes PHLIS to call the communications computer, log the user on with appropriate identification, upload the data, indicate whether data have been transferred correctly, and log off. No experience is needed with telecommunications to accomplish transfer of data electronically. Data may be transmitted as often as necessary (multiple times in the same day if desired).

Transmitted data are downloaded to the CDC mainframe, where processing and edits are performed by the responsible program. If errors are detected, edits are transmitted back to reporting sites. Messages and tables summarizing data received at CDC are downloaded to sites. The TELECOMMUNICATIONS option (Figure 8) provides access to other CDC systems, and bulletin board script files contain telephone numbers that PHLIS accesses when connecting to other systems. Therefore, PHLIS can connect to additional services as requested by state officials (e.g., E-Mail).

FIGURE 4—*Salmonella* human isolates data entry screen.

Discussion

PHLIS has immediate benefits for public health: (1) Electronic transmission of reports reduces the paper and data entry burdens within states (in one state, the same reports of *Salmonella* are routinely entered into three computers and again at CDC). (2) Access to timely national summaries ensures that data are current and responses to inquires at local, state, and CDC levels are timely. (3) PHLIS increases interaction among public health officials, stimulates more thorough reporting, and fosters greater awareness of reporting problems. Finally, rapid reporting provides the potential to quickly identify unusual disease clusters and alert state epidemiologists and CDC personnel to outbreak episodes. However, the need for careful field investigation and data assess-

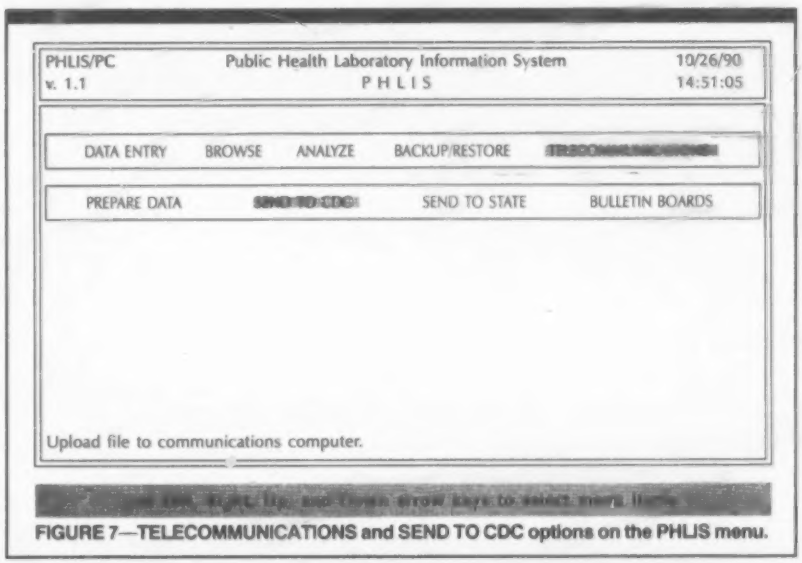

FIGURE 7—TELECOMMUNICATIONS and SEND TO CDC options on the PHLIS menu.

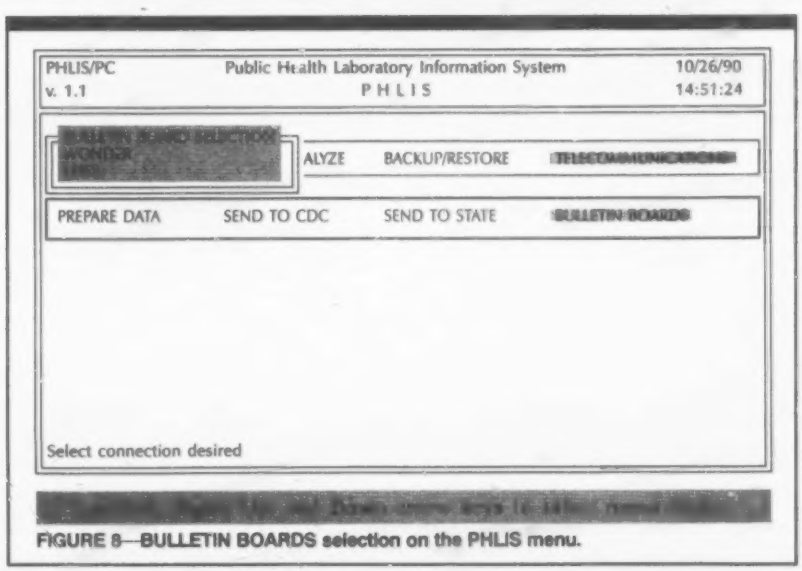

FIGURE 8—BULLETIN BOARDS selection on the PHLIS menu.

ment prior to data entry remains the responsibility of the originating site.

PHLIS can be implemented without the telecommunications components; data can be transferred as ASCII files via modems among sites without a central computer to receive data; and organizations without modems can transmit data via diskettes without affecting system integrity.

PHLIS is currently installed in 41 of the 45 state laboratories that have requested the system. Although the initial PHLIS module was implemented using laboratory-based data, the system accommodates all data types (e.g., epidemiological data). Three additional laboratory modules have been added to the system (*Shigella, Campylobacter,* and *Mycobacteria*), as well as one module to collect epidemiological data from state epidemiologists' offices (seafood case-control study).

PHLIS was designed to provide flexibility with few constraints placed on module design and data transfer. Plans for enhancements include development of an "applications generator" that allows users to develop new modules or make modifications to accommodate unique site needs. PHLIS is available without cost to any organization wishing to implement the system. □

Acknowledgments

Portions of this material were presented at the 32nd Annual Planning Conference of the Association of State and Public Health Laboratory Directors, 1989, and the annual meeting of the Council of State and Territorial Epidemiologists, 1990.

We thank the Management Information Systems Committee of the Association of State and Territorial Public Health Laboratory Directors for their guidance and support, Sara Lyle for computer programming for PHLIS, and the personnel in the seven pilot states for their participation.

Homosexual and Bisexual Men's Perceptions of Discrimination in Health Services

Nancy E. Kass, ScD, Ruth R. Faden, PhD, MPH, Robin Fox, MS, and Jan Dudley, MPH

ABSTRACT

Questionnaires were distributed to homosexual and bisexual male participants in the Multicenter AIDS Cohort Study and to homosexual and bisexual male patients with acquired immunodeficiency syndrome (AIDS) to determine whether the men believed they had been refused medical or dental treatment because of their sexual orientation or a condition related to the human immunodeficiency virus (HIV). Men with AIDS were significantly more likely (18%) to report being refused treatment by a doctor or dentist on the basis of a known or suspected HIV-related condition than were men who were seropositive (5%) or seronegative (1%). Significantly more respondents reported refusal of dental care than of medical care. (*Am J Public Health.* 1992;82:1277–1279)

Introduction

Since the beginning of the human immunodeficiency virus (HIV) epidemic, there have been reports of discrimination toward HIV-infected persons in many settings,[1–5] including the health care setting.[6–8] Moreover, there have been reports of discrimination in the provision of health services on the basis of patients' sexual orientation; this discrimination is thought to be at least partially related to the association between male homosexuality and risk of HIV infection. Refusal to provide health services is an important ethical issue and is contrary to professional standards. Moreover, refusal of treatment becomes a public health issue when unjustified discrimination results in diminished access to health services.

Although various studies have documented physicians' and dentists' attitudes toward HIV-infected patients,[9–12] and homosexual patients,[9,13] little empirical work has been conducted to determine the experiences of at-risk individuals seeking medical or dental care. It was the purpose of this study to document the extent to which homosexual and bisexual men believe they have been refused services by a doctor or dentist because of their sexual orientation or because of a known or suspected HIV-related condition.

Methods

Study Populations

Three different samples were used in this study. Samples 1 and 2 were recruited from the Baltimore and Los Angeles sites, respectively, of the Multicenter AIDS Cohort Study (MACS). Sample 3 was recruited from gay and bisexual male AIDS patients at The Johns Hopkins Hospital in Baltimore.

The MACS, begun in 1984, is a prospective study of the natural history of HIV infection in gay and bisexual men. Criteria for initial inclusion in the MACS were being male, having a history of homosexual or bisexual activity, and not having acquired immunodeficiency syndrome (AIDS) at the time of enrollment. Most of the men in this volunteer cohort have college degrees (Baltimore, 67%; Los Angeles, 55%) and are White (Baltimore, 92%; Los Angeles, 91%).[14]

MACS appointments are scheduled every 6 months. Baltimore and Los Angeles MACS participants were asked to complete the questionnaire for this study during their eighth visit (between October 1987 and July 1988). In Baltimore, 857 men attended the clinic during the study period. There was a response rate of 93%; therefore, 797 participants constituted sample 1. Because other studies were being conducted at the Los Angeles site during that time, there was only a 19% response rate on site. Therefore, questionnaires were mailed to the remaining Los Angeles MACS participants. There was an overall response rate of 59% from the 1250 participants scheduled for a visit during this period. Thus, sample 2 consisted of 708 Los Angeles MACS participants.

Sample 3 consisted of gay and bisexual male inpatients and outpatients with AIDS at The Johns Hopkins Hospital; these patients were recruited because the number of participants in the MACS with AIDS was small. Patients who were too sick to complete a questionnaire were interviewed. Of 63 patients approached, 59 (94%) agreed to participate, constituting sample 3.

Has a dentist ever refused to treat you because s/he suspected that you were HIV positive or had an AIDS-related illness?****	1	4	16

*$P < .05$ for difference between seronegative men (SNs) and seropositive men (SPs) (odds ratio [OR] = 2.5; 95% CI = 1.3, 4.8).
**$P < .01$ for difference between persons with AIDS (PWAs) and SNs (OR = 7.8; 95% CI = 2.9, 26.1); $P < .01$ for difference between SPs and SNs (OR = 3.9; 95% CI = 1.5, 10.1).
***$P < .05$ for difference between PWAs and SNs (OR = 3.7; 95% CI = 1.1, 11.9); $P < .05$ for difference between SPs and SNs (OR = 2.4; 95% CI = 1.1, 5.2).
****$P < .001$ for difference between PWAs and SNs (OR = 22.2; 95% CI = 8.8, 55.9); $P < .001$ for difference between SPs and SNs (OR = 4.7; 95% CI = 2.0, 11.0).

The Research Instrument

Questions for this investigation constituted one section of a larger self-administered questionnaire concerning insurance status and perceived discrimination. In this section, participants were asked four yes/no questions concerning treatment refusal by doctors or dentists (Table 1).

Data Obtained from MACS Records

Data collected specifically for this study were linked with data collected by the MACS at the same or most recent clinic visit, including demographic characteristics; HIV antibody status; AIDS diagnosis; CD4 count; and self-reported weight loss, fevers, fatigue, and diarrhea. (Because the men in sample 3 were not part of the MACS, questionnaires distributed to this group included questions on demographics.)

Statistical Analyses

Two-tailed Fisher's Exact Tests were used to compare respondents with nonrespondents with respect to demographic and health-related characteristics and to test the association between each type of treatment refusal and (1) HIV antibody status and (2) certain demographic characteristics. For bivariate relationships found to be associated with a probability higher than 95%, odds ratios and 95% confidence intervals were calculated. Logistic regression was used to develop predictive models.

Results

Comparison of Respondents with Nonrespondents

Respondents and nonrespondents from Samples 1 and 2 were compared using available MACS data. Respondents were more likely to be White, well educated, and older. Nonrespondents were more likely to be seropositive or to have AIDS. There were no significant differences between respondents and nonrespondents in terms of selected symptoms, CD4 count, or history of hospitalization since their last visit.

Comparison of MACS Participants with Johns Hopkins Participants

Persons with AIDS (PWAs) from the MACS were compared with PWAs recruited from The Johns Hopkins Hospital in terms of educational background and employment status. Although no differences were significant at $P < .05$, PWAs recruited from Johns Hopkins tended to be somewhat less well educated (67% had at least some college education, compared with 88% of PWAs from the MACS) and were more likely to be employed full-time (78%, compared with 67% of PWAs from the MACS).

Treatment Refusals Based on Sexual Orientation

Two percent of the seronegative men (SNs) reported having been refused treatment by a doctor because of the respondent's sexual orientation, compared with 4% of seropositive men (SPs) who did not have AIDS ($P < .05$) and 3% of PWAs. One percent of SNs reported having been refused treatment by a dentist because of the respondent's sexual orientation, compared with 3% of SPs ($P < .05$) and 4% of PWAs ($P < .05$) (Table 1).

Treatment Refusals Based on HIV-Related Conditions

One percent of SNs reported having been refused treatment by a doctor because of a known or suspected HIV-related condition, compared with 3% of SPs ($P < .01$) and 5% of PWAs ($P < .01$). One percent of SNs reported having been refused treatment by a dentist because of a known or suspected HIV-related condition, compared with 4% of SPs ($P < .001$) and 16% of PWAs ($P < .001$).

One percent of SNs reported having been refused treatment by either a doctor or a dentist because of a known or suspected HIV-related condition, compared with 5% of SPs ($P < .001$) and 18% of PWAs ($P < .001$). The same degree of treatment refusal was reported by PWAs from the MACS and by PWAs from The Johns Hopkins Hospital. In the logistic model, having AIDS and being seropositive each contributed independently to predicting treatment refusal from a doctor or dentist on the basis of a known or suspected HIV-related condition; age, education, and symptoms were not significant predictors.

Discussion

Whereas homosexual and bisexual men without AIDS very rarely reported treatment refusals, 18% of PWAs reported a refusal from a doctor or dentist on the basis of a known or suspected HIV-related condition. However, refusal of dental care was considerably more likely to be reported than refusal of medical care.

A limitation of this study is that all data are self-reported, and responses were not validated. We do not know the circumstances of the incidents, or if the practitioners would have described the interactions in the same way as did the respondents. Participants may have characterized any difficulty they had in securing access to services as a refusal when other reasons truly existed; moreover, men who had ex-

perienced refusal may have been more likely to respond to our questionnaire. Either of these possibilities could result in overreporting. However, many participants volunteered that they had deliberately sought care from gay practitioners to avoid discrimination problems. In addition, SPs and PWAs were more heavily represented among nonrespondents in our sample. Both of these factors could lead to underreporting of treatment refusal.

Treatment refusals may exacerbate the existing disproportionate public burden of care and treatment costs for persons infected with HIV. The disproportionate number of PWAs in this study who reported a treatment refusal, particularly by dentists, is cause for concern and warrants public health and public policy attention. □

Radiologic Society Conference to Be Held in Late November

The 78th Scientific Assembly and Annual Meeting of the Radiological Society of North America (RSNA) will be held November 27 to December 4, 1992, at McCormick Place in Chicago, Ill. More than 1400 scientific papers will be presented this year, from clinical studies in radiation therapy to new procedures in ultrasound, MRI, CT, SPECT, and PET scans. In addition, there will be nearly 1000 technical and scientific exhibits.

More than 50 000 health care professionals from more than 80 countries are expected to attend, making the conference the largest radiology meeting in the world. For registration, contact RSNA at 2021 Spring Rd, Suite 600, Oak Brook, IL 60521; tel. (708) 571-2670, fax (708) 571-7837.

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc, 1015 Fifteenth St, NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50 000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health,* 1015 Fifteenth St, NW, Washington, DC 20005.

Information on Manuscript Preparation is published monthly in the Journal. The Journal publishes reports of original research, research methods, program evaluations, analytic reviews, including health policy analysis, and reports for special departments. A paper is considered with the understanding that it or its essential substance neither has been published nor is under consideration elsewhere.

Subscription price, individual, is $100/year US, $140/year international; **institutional,** $160/year US, $200/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to *American Journal of Public Health,* 1015 Fifteenth St, NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Schultz, Advertising Manager, APHA, 1015 Fifteenth St, NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Commentary: The Public Health Consequences of Restricted Induced Abortion—Lessons from Romania

Patricia Stephenson, ScD, Marsden Wagner, MD, MSPH, Mihaela Badea, MD, and Florina Serbanescu, MD

ABSTRACT

The question of whether abortion should be legal is currently being decided in many countries. Although much of the discussion has focused on ethical issues, the public health consequences should not be overlooked and should be addressed realistically and responsibly. Nowhere are the public health manifestations of restricted abortion more apparent than in Romania. The pronatalist policies of the Ceaucescu regime resulted in the highest maternal mortality rate in Europe (approximately 150 maternal deaths per 100 000 live births) and in thousands of unwanted children in institutions. (*Am J Public Health.* 1992;82:1328–1331)

Introduction

Abortion policy is being debated in a number of countries in which abortion is currently legal and women have access to safe abortion, performed by qualified practitioners, through the health care system. Some political or religious groups in Hungary, Poland, Germany, Spain, Sweden, and the United States seek to ban abortion or at least to restrict it as much as possible.

Both proponents and opponents of legal abortion debate the issue in the abstract terms of women's rights, fetal rights, religious theories, or constitutional principles. However, those who ultimately decide this question will sooner or later have to come to terms with the concrete reality of what can happen to women and children when and if the right to safe abortion is taken away.

Safe Abortion and Maternal Mortality

When access to safe abortion has been introduced in a country, maternal mortality has decreased. In the United States during the 1960s, as some states began to change their laws on abortion and hospital abortion policies became less restrictive, gradual decreases in maternal mortality were noted. After the US Supreme Court decision in 1973 guaranteeing women the right to safe abortion, national maternal mortality rates decreased further. In England and Wales there were no deaths due to unsafe abortion in the triennium 1982 to 1984, compared with 75 to 80 such deaths per triennium prior to the Abortion Act of 1967 (which gave free access to safe abortion).[1] Although it is reasonable to conclude that these trends are due to the changes in the abortion laws, one can never completely rule out the possible simultaneous effects of other factors.

More instructive is what happens in a country when abortion is made illegal and access to safe abortion taken away. Before 1966, Romanian women—like their neighbors in other Eastern European countries—had access to safe abortion through the country's health care system. In 1966 Romanian President Nicolae Ceaucescu introduced pronatalist policies, outlawed abortion and contraception, and took measures to enforce the law. Mandatory pelvic examinations at places of employment were imposed on women of reproductive age. Informers for the security police were stationed in maternity hospitals. Doctors could be prosecuted for performing unauthorized abortions, and nurses were to make unannounced supervisory visits to new mothers to determine whether they were taking proper care of their infants.

The consequences of this policy and its enforcement are presented in Figures 1 through 3, through data from the Romanian birth and death registration system and the nationwide, ongoing maternal mortality audit system. (World Health Organization site visits from 1991 to 1992 have found that these systems are comparable to those of Western Europe in terms of the completeness of reporting and the reliability of data.[2] Romanian vital data systems and maternal mortality reports use ICD-9 CM definitions

Patricia Stephenson is with the Centrum for Folkhälsoforskning, Karlstad, Sweden. Marsden Wagner is retired from the World Health Organization, European Regional Office, Copenhagen, Denmark. Mihaela Badea is with the Ministry of Health of Romania, Bucharest, Romania. Florina Serbanescu is with the Institute for Mother and Child, Bucharest, Romania.

Editor's Note. See related editorial by Susser (p 1323) in this issue.

and diagnostic classifications.) After a brief rise, the crude birth rate fell and continued to fall (Figure 1). Thus the policy intended to increase the birth rate failed.

Before the 1966 law went into effect, the Romanian maternal mortality rate was similar to those of other Eastern European countries. Afterward, abortion-related maternal mortality increased to a level 10 times that of any other European country (Figures 2 and 3). For the decade 1980 to 1989, the average Romanian maternal mortality rate was 150 maternal deaths per 100 000 live births.[6] Many women obtained abortion illegally, and every year approximately 500 otherwise-healthy women of childbearing age died from postabortion hemorrhage, sepsis, abdominal trauma, and poisoning.

Precise figures on the Romanian prevalence of postabortion morbidity are not available. The country's most common causes of obstetrical death were postpartum hemorrhage and infection,[3] complications that could be associated with unsafe abortion. In Romania, local health professionals report that unsafe abortion—as performed by the woman herself or by untrained persons—may involve very dangerous techniques, such as scraping the uterus with a rubber tube or other instrument, uterine lavage with water or a caustic fluid, introduction of foreign bodies into the uterus, or external trauma. Such methods often result in damage to the uterine cervix, chronic infection, and severe anemia that, in turn, increase the risk of postpartum hemorrhage and infection, infertility, preterm birth, and low birthweight.[7,8]

FIGURE 1—Crude birth rate, crude death rate, and rate of natural increase, Romania, 1966 to 1991.

The Social Impact of Restricted Abortion

Legions of Romanian children in institutions are another sad legacy of the years of the Ceaucescu pronatalist policy. Some women who did not have illegal abortions bore children after unwanted pregnancies and placed the children in institutions because they and their families simply could not find the means or motivation to care for them.[9] Although the number of children institutionalized before the overthrow of the Ceaucescu government is unknown, shortly after the revolution approximately 150 000 to 200 000 children were in institutional care.[10] Warehousing of children in institutions overwhelmed the health care system and reduced the standard of care.[9] Present programs have returned many institutionalized children to their families or have attempted to place them in adoptive homes.[9] However, several thousand severely retarded and handicapped children are likely to remain in institutions for the rest of their lives.[9]

Conclusions

After the December 1989 Romanian revolution, one of the provisional government's first acts abrogated the 1966 law banning abortion and contraception. This was done as an emergency public health measure to try to decrease maternal mortality due to unsafe abortion. Since then, more and more induced abortions have been performed by qualified doctors in hospitals or clinics; the maternal mortality rate fell by 50% in the first year following the change in the law. It continues to fall as more and more women avail themselves of safe abortion. New admissions to children's institutions have decreased in spite of severe economic conditions.[9]

The Romanian experience demonstrates the futility and folly of attempts to control reproductive behavior through legislation. A law that forbids abortion does not stop women from aborting unwanted pregnancies. In Ireland today, where abortion is illegal, some 4000 women each year travel to Britain for the procedure. Nor can laws concerning reproductive behavior be effectively enforced. The extreme pronatalist policies in Romania did not succeed in sustaining the desired levels of reproduction and natural increase (Figure 1).

To reduce or eliminate abortion, the rational approach is to promote contraception. To paraphrase the position statement of the 1984 International Conference on Population, the solution to the abortion question is to prevent unwanted pregnancy.[7] The outlawing of abortion and contraception is not pronatalist but antinatalist in that the results are likely to be fewer healthy, fertile women who might have children, reduced fertility from widespread gynecological infection, the birth of more damaged babies, and, in sum, not more but fewer healthy citizens for the future.

In the 23 years of its enforcement, the antiabortion law in Romania resulted in over 10 000 deaths of women from unsafe abortion. The pronatalist policy as a whole resulted in the untoward institutionaliza-

FIGURE 3—1989 maternal mortality rate for 12 European and Asian countries.

tion of thousands of children and in an elevated rate of infant deaths. In effect, it also turned otherwise–law-abiding women and their partners into criminals; women learned to fear the government and its representatives. Doctors and other health care providers were victims as well because they were forced to carry out the policies of the state. Working today to improve and strengthen women's health services, Romanian doctors report that many women remain fearful of contact with the health care system.

The lessons of the Romanian experience hit home for those of us who remember how it was in our own countries prior to the legalization of abortion. Those who could afford to fly to other places could obtain legal, safe abortion, while those who could not made do with "backstreet" procedures or relinquished their unwanted children to orphanages. Perhaps we have come so far and accomplished so much that we have forgotten the public health consequences of restricting access to safe abortion.

In light of those consequences, it does not matter whether, as health professionals, we believe that life begins at conception or whether 8-week-old fetuses should have equal protection under the law. Policy on abortion is being formulated in the rarified atmosphere of legislatures and parliaments, meeting halls and court rooms. Let us hope that policymakers accept their responsibility for protecting the health and lives of women and children. □

Public Health Policy Forum Submissions Invited

The "Public Health Policy Forum," a new feature of the Journal, is intended to provide a presentation of divergent views on important public health policy issues that is more extensive than the Journal's format usually allows. Three kinds of material will appear in the Public Health Policy Forum: articles, not to exceed 4500 words; commentaries, not to exceed 2500 words; and editorials. Customarily, commentaries and editorials will be solicited by the Journal's Associate Editor or Editor. Articles for the Public Health Policy Forum will be selected from articles submitted to the Journal and, on occasion, from those submitted directly to the Associate Editor. In general, peer review will still be sought.

Those wishing to submit articles directly to the Associate Editor may do so at this address:

Bruce C. Vladeck, PhD
The United Hospital Fund
55 Fifth Avenue
New York, NY 10003-4392

Five copies of the article should be submitted simultaneously to the Journal's Washington, DC, office.

The scholarly merit and the scientific accuracy of all submissions will be considered. Additional criteria are relevance to an important policy issue, timeliness, and clarity and coherence of the policy argument. Brevity also helps considerably.

Determinants of Depressive Symptoms in the Early Weeks after Miscarriage

Richard Neugebauer, PhD, MPH, Jennie Kline, PhD, Patricia O'Connor, PhD, Patrick Shrout, PhD, Jim Johnson, PhD, Andrew Skodol, MD, Judith Wicks, BA, and Mervyn Susser, MB, BCh, FRCP(E), DPH

ABSTRACT

Objectives. We tested whether and under what conditions miscarriage increases depressive symptoms in the early weeks following loss.

Methods. We interviewed 232 women within 4 weeks of miscarriage and 283 pregnant women and 318 community women who had not recently been pregnant. Depressive symptoms were measured with the Center for Epidemiologic Studies Depression (CES–D) Scale.

Results. Among women who had miscarried, the proportion who were highly symptomatic on the CES–D was 3.4 times that of pregnant women and 4.3 times that of community women. Among childless women, the proportion of women who had miscarried who were highly symptomatic was 5.7 times that of pregnant women and 11.0 times that of community women. Women who had miscarried were equally depressed regardless of length of gestation; among pregnant women, depressive symptoms declined with length of gestation. Among women who had miscarried, symptom levels did not vary with attitude toward the pregnancy; among pregnant women, depressive symptoms were elevated in those with unwanted pregnancies. Prior reproductive loss and advanced maternal age (35+ years) were not associated with symptom levels in any cohort.

Conclusions. Depressive symptoms are markedly increased in the early weeks following miscarriage. This effect is substantially modified by number of living children, length of gestation at loss, and attitude toward pregnancy. (*Am J Public Health.* 1992;82:1332–1339)

Introduction

Twelve to fifteen percent of clinically recognized pregnancies end in spontaneous abortion;[1] approximately half a million women miscarry annually in the United States alone.[2] For many women, miscarriage is an unanticipated and physically traumatic event signaling an abrupt disruption of reproductive plans. It may also prompt doubts about reproductive competence and thereby provoke a loss of self-esteem. Despite these considerations and repeated calls in the medical and lay literature for studies of the emotional effects of reproductive loss,[3–6] systematic observational studies of the psychological impact of miscarriage are rare. We have located only four published studies that focused exclusively on miscarriage,[7–10] and six that included miscarriage in an investigation of perinatal death.[11–16] In general, these studies are compromised by small sample sizes that limit both the generalizability of their results and the use of statistical adjustment for potentially confounding factors. More importantly, these investigations' lack of a comparison group unexposed to recent reproductive loss precludes determination of the overall size of the effect of miscarriage on psychiatric symptoms and the role of potentially moderating factors, such as maternal age and number of living children.

The frequency of miscarriage as an adverse reproductive outcome and the expectation that it will raise maternal risk for depressive symptoms makes assessment of its psychological impact an important public health question. We investigated whether and under what conditions miscarriage was associated with a substantial increase in depressive symptoms. In this paper we report results for the first few postabortion weeks. We hypothesized that miscarriage would raise the level of depressive symptoms in this early period after loss and that the magnitude of the effect would vary with characteristics of the woman, her pregnancy, her attitude toward the pregnancy, and her reproductive history. Specifically, we hypothesized that the effect of miscarriage would be greater in women with few or no living children, in those with a history of prior reproductive loss, in those with a positive attitude toward the pregnancy, and in those aged 35 years or older. Further, we hypothesized that the impact of miscarriage would increase with length of gestation at the time of loss. We tested these hypotheses by comparing levels of depressive symptoms in women who had miscarried with those in

This paper was submitted to the Journal May 29, 1991, and accepted with revisions May 22, 1992.

two other groups of women, both unexposed to recent reproductive loss.

Methods

Study Design

The study comprised three cohorts: women who had miscarried, currently pregnant women, and women in the community who had not been pregnant in the preceding year. The pregnant cohort afforded an estimate of the level of depressive symptoms to be expected in an uninterrupted pregnancy; the community cohort, the level of such symptoms in the absence of any recent reproductive event.

Miscarriage and Pregnant Cohort

In this study miscarriage is defined as the involuntary termination of a nonviable intrauterine pregnancy before 28 completed weeks of gestation. The miscarriage and pregnant cohorts were taken from the case subjects and control subjects, respectively, of a hospital-based case-control investigation of risk factors for miscarriage.[17] The case-control study attempted to interview all women attending a New York City hospital for a miscarriage (cases) from late 1984 to 1986. The control patients were drawn from women registered for prenatal care before 22 weeks' gestation and selected to be similar to case subjects in age and payment status (i.e., private or public).[18] The case-control study succeeded in interviewing 81% of identified case and control subjects. Among women who had miscarried and pregnant women, interviewed and uninterviewed subjects in the case-control study were distributed similarly on sociodemographic and reproductive characteristics.[17,19]

At the conclusion of the case-control interview, women who had miscarried and pregnant women who were 18 years old or older, English- or Spanish-speaking, and accessible by telephone were invited to enter the present investigation, which was separate from the case-control study. For pregnant women, we required further that the case-control interview occur before 28 completed weeks' gestation.

For the present study, we interviewed 232 women within 4 weeks of miscarriage; 85% were interviewed between days 7 and 15 after loss (Table 1). These women represented 70% of the eligible subjects then available from the case-control study. (Of the remainder, approximately half declined to participate altogether. The rest could not be scheduled for an interview within this narrow time frame but were evaluated in subsequent months. Together with later recruits from the case-control study, these subjects constitute material for a separate report.[20])

Seventy-two percent (283) of the eligible pregnant women were interviewed, most in their second trimester. Twenty percent refused to participate in the study; the remainder postponed the study interview beyond 28 weeks' gestation. Interviewing of women who had miscarried and pregnant women was concluded in 1987.

Community Cohort

Recruits for the community cohort were located by random dialing of telephone numbers. They were residentially stratified by the area codes and exchanges of interviewed women who had miscarried. A screening interview determined whether an eligible subject—a woman aged 18 to 44 years who had not been pregnant in the preceding 12 months—resided at the location. (Eligibility status was determined for 92% of working telephone numbers.) Community women were frequency-matched to the miscarriage cohort on language and season of interview, age (in 5-year intervals), and education (less than high school, high school graduate, college graduate, postgraduate training). Ethnicity was also recorded. Eighty-two percent (318) of known eligible community women were interviewed; the remainder declined to participate in the study. Community interviews were conducted in 1986 and 1987.

Comparability of Interviewed and Uninterviewed Study-Eligible Subjects

Within each cohort, interviewed and all uninterviewed eligible women were generally similar in age, ethnicity, education, and language and season of interview. Interviewed and uninterviewed women who had miscarried and pregnant women (on whom additional sociodemographic data were available from the case-control study) did not differ in marital status, parity, length of gestation or prior reproductive loss. However, as we will explain, public patients with miscarriages were given priority when in-hospital interviews in the case-control study were scheduled. As a result, among miscarrying subjects, women interviewed in the early weeks after loss tended to be disproportionately Black and Hispanic and less educated than uninterviewed women.

At the time of recruitment, women who had miscarried and pregnant women entering in the second half of the study, and all community women, were administered a version of an established single-item measure of depressed mood.[21] Within each cohort, the adjusted mood scores of interviewed and uninterviewed women were indistinguishable, suggesting that the affective state of the women successfully interviewed in our study was representative of study-eligible women generally.

Study Measures

Depressive symptoms were evaluated by means of the Center for Epidemiologic Studies Depression (CES–D) Scale,[22] a 20-item symptom checklist that asks about the presence and duration of symptoms in the preceding 7 days. This scale measures affective and somatic aspects of depressive symptomatology and low self-esteem. Scale items offer a fixed, alternative-choice format for subjects' responses regarding symptom frequency, scored from 0 ("rarely") to 3 ("most of the time"); item scores are summed to produce an overall index. The CES–D correlates well with other self-report measures of depressive symptoms, distinguishes clinically depressed patients from the general population,[22–24] and has been used previously with samples of pregnant women.[25] The CES–D scores of our subjects were associated with their scores on the single-item measure of mood administered several weeks earlier. Internal consistency reliabilities (Cronbach's alpha) of the CES–D in our three study cohorts overall and in language, ethnic, and educational subgroups within cohorts are excellent (.83 to .92).

We assessed attitudes toward the pregnancy in women who had miscarried and pregnant women with three items concerning the woman's wish to conceive, her emotional reaction to learning of her pregnancy, and her consideration of elective abortion. A subject's score could range from 0 to 12. A woman who had been trying to conceive, who reported being "very happy" when she learned she was pregnant, and who had given no thought to an elective abortion received a score of 12. A woman who did not want to become pregnant, who indicated being "very unhappy" about being pregnant, and who had actually scheduled an elective abortion before she miscarried scored 0. The internal consistency reliabilities of this scale in our two obstetric cohorts overall and in sociodemographic sub-

Note. Differences among the three groups were evaluated by an overall chi-square test for categorical variables and by a one-way analysis of variance for continuous variables.
[a]Includes spontaneous abortions (89.6%), fetal deaths (3.7%), ectopic pregnancies (3.2%), and neonatal deaths (3.4%).
[b]For the miscarriage cohort, the gestation interval refers to the time from last menstrual period (LMP) to date of expulsion of the conceptus; for pregnant women, the interval is from LMP to the miscarriage study interview. First trimester = ≤ 13 completed weeks' gestation; second trimester = 14 through 26 completed weeks' gestation; third trimester = > 26 completed weeks' gestation.
*$P < .05$. **$P < .01$.

groups are acceptable (.68 to .78). More importantly, the scale correlated strongly with contraceptive use, pregnancy status, and reproductive plans at 6 months after loss, thereby affording evidence of its predictive validity in the miscarriage cohort and suggesting that subjects were not simply reporting positive, more socially acceptable attitudes toward their pregnancies.

Procedure

The CES–D, together with the remainder of the interview questions covering reproductive history, sociodemographic characteristics, and aspects of social functioning, was administered by telephone. The general comparability of sociodemographic, psychiatric symptom, and medical history data obtained from telephone and in-person interviews is well documented.[26-28]

The content of the interview precluded blinding interviewers to subjects' group membership. However, the possibility that interviewers influenced subjects' responses was minimized by the use of a fully structured questionnaire with fixed response options and monthly training sessions proscribing ad hoc interviewer probes. Compliance with this aspect of the study protocol was confirmed by periodic auditing of taped interviews by the first author.

Analytic Strategy

CES–D depressive symptom levels are reported in terms of symptom means for each cohort and in terms of proportions of women who were highly symptomatic. Women were considered highly symptomatic if they received CES–D scores of 30 or more, which meant that they reported having at least half of the 20 depressive symptoms most of the time for a week or longer. Analyses using these proportions assessed whether findings based on the entire range of symptom scores held true for extreme symptom levels. Approximately two thirds of the women scoring ≥30 would be expected to meet diagnostic criteria for major depressive disorder.[29]

For descriptive purposes, the observed CES–D means for each cohort overall and by selected characteristics are provided at the outset (Table 2). Comparison of means within cohorts is accomplished with one-way analyses of variance.

Formal analyses of differences in means and proportions across cohorts were conducted using ordinary least squares multiple regression and maximum likelihood logistic regression, respectively, to permit adjustment for potentially confounding variables. Candidate variables for adjustment in these multivariate analyses were drawn from an a priori list of potential confounding variables (e.g., marital status) and moderating variables (e.g., maternal age). (The matching variables for the community cohort were also introduced as covariates, both as main effects and as all possible two-way interaction effects. The latter terms did not materially influence the regression coefficients of interest here. Hence, for parsimony they are omitted from the final regression equations.) Screening for potential confounders in the data set (with reference to the

remaining characteristics, listed in Table 1) did not disclose other variables requiring analytic control. The regression equations comparing the women who miscarried and the community women contained the following terms: marital status, maternal age (linear), ethnicity, socioeconomic status (using a standardized index that assigns equal weight to maternal education and family income), number of living children, and prior reproductive loss. Equations comparing the women who miscarried and the pregnant women added payment status, length of gestation at miscarriage/interview (linear), and attitude toward the pregnancy.

Results from the least squares regression analyses are presented in the form of the difference in adjusted means between the miscarriage cohort and a comparison cohort; results from logistic regression analyses are presented as the ratio of the adjusted proportion of highly symptomatic women in the miscarriage cohort to the adjusted proportion of highly symptomatic women in a comparison cohort (Table 3).[30] (Corresponding odds ratios are provided in the notes to the relevant table.) The association of a particular characteristic, for example, number of living children, with depressive symptoms within each cohort is measured by the unstandardized regression coefficient *b* (see Figure 1 notes). The slope *b* indicates the change in CES-D score per unit change in the characteristic of interest. The possibility that the effect of miscarriage varies with the number of living children or, specifically in the miscarriage-pregnant comparison, with length of gestation or attitude toward pregnancy, was tested as a first-order interaction term in the regression analysis. Significant interaction terms were introduced as "centered" terms into all equations from the outset. For example, in calculating the adjusted difference in CES-D means between women who miscarried and pregnant women (Table 3), the estimated differences between cohorts were represented at the mean values for number of living children, length of gestation, and attitude toward the pregnancy.

Unless indicated otherwise, statistical significance is assessed at $P < .05$.

For age, education, number of living children, number of prior reproductive losses, length of gestation, and attitude toward pregnancy, *P* values pertain to two-tailed ANOVA tests for linearity, using 1 degree of freedom.

[a]First trimester = ≤ 13 completed weeks' gestation; second trimester = 14 through 26 completed weeks' gestation; third trimester = > 26 completed weeks' gestation.

[b]In both the pregnant and miscarriage cohorts, roughly 15% of the women indicated unequivocally that they did not want the pregnancy. Approximately 55% indicated exclusively positive feelings of wanting the pregnancy, and the remainder expressed some reservations about their pregnancies.

*$P < .10$; **$P < .05$; ***$P < .01$; ****$P < .001$.

Sample Characteristics

Community women were selected to be sociodemographically similar to all interviewed women who had miscarried, including those assessed only in later months of the study. However, the case-control study gave priority to conducting in-hospital interviews with miscarrying women who were public patients; private patients were judged easier to reach after discharge. As a consequence, public patients are overrepresented among women interviewed in the present study in the early postabortion weeks. Therefore, the miscarriage cohort in this report differs from the other two groups in those characteristics associated with payment status, for example, ethnicity and educational level (Table 1). Also, as expected, the two obstetric cohorts contain a lower

TABLE 3—Center for Epidemiologic Studies Depression Scale (CES–D) Means and Proportions of Highly Symptomatic Women

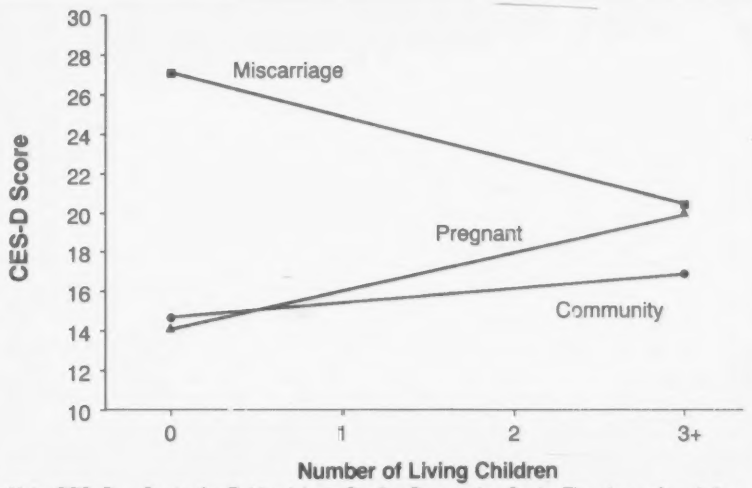
[a]Means are adjusted by ordinary least squares multiple regression analysis, proportions by maximum likelihood logistic regression analysis.
[b]The odds ratio for this comparison is 4.9 (95% CI = 2.4, 10.0).
[c]The odds ratio for this comparison is 6.2 (95% CI = 3.8, 10.5).



Note. CES–D = Center for Epidemiologic Studies Depression Scale. The slope of each line (*b*) represents the unstandardized regression coefficient for the term for number of children, from within-cohort least squares multiple regression. In the pregnant cohort, $b = 1.3$ per child (95% CI = −0.1, 2.8), $P < .11$; in the miscarriage cohort, $b = -2.1$ per child (95% CI = −3.8, −0.3), $P < .02$; in the community cohort, $b = 0.73$ per child (95% CI = −0.72, 2.2), $P < .32$. The interaction term in the pregnant/miscarriage analysis (cohort by number of children) is significant at $P < .002$. The interaction term in the community/miscarriage analysis is significant at $P < .0004$.

FIGURE 1—Number of children and adjusted CES–D scores in miscarriage, pregnant, and community cohorts.

proportion of nulliparous women and a higher proportion of women with prior reproductive loss than does the community cohort. The regression analyses adjust satisfactorily for the possible effect of these sociodemographic and reproductive history differences between cohorts on depressive symptoms.

Results

Overall CES–D Means and Proportions of Women Highly Symptomatic

Depressive symptom levels were higher in women who had miscarried than in women in the pregnant and community cohorts. The observed symptom mean of the miscarriage cohort was 24.0 (Table 2); 36.2% of the subjects were highly symptomatic (Table 3). In adjusted analyses, the mean of the miscarriage cohort exceeded those of the pregnant and community cohorts by 7.5 and 9.1 points, respectively (Table 3). Similarly, in adjusted analyses, the proportion of subjects highly symptomatic in the miscarriage cohort was 3.4 and 4.3 times the proportion in the pregnant and community cohorts, respectively (Table 3).

Number of Living Children

The presence of children strongly influenced the effect of miscarriage on depressive symptoms. In the pregnant and community cohorts, the observed symptom means exhibit a significant increase with an increase in the number of children. By contrast, in the miscarriage cohort, depressive symptoms declined with increasing numbers of children (Table 2). These differences are sustained in multivariate analyses. The slopes of the regression lines representing the association of numbers of children with depressive symptoms differ markedly between the pregnant and miscarriage cohorts (Figure 1). Therefore, despite the overall difference in symptom levels between pregnant women and women who had miscarried, average symptom levels did not differ between miscarrying and pregnant women with several children. The same pattern holds in the comparison of the miscarriage and community cohorts (Figure 1).

To delineate further an especially high-risk group, we dichotomized our subjects into those with and without children. Forty percent of the childless women who miscarried were highly symptomatic. In adjusted analyses, this proportion is 5.7 times that of childless pregnant women (95% CI = 2.5, 8.9) and 11 times that of childless community women (95% CI = 5.6, 16.7). Among women with children, the proportion highly symptomatic was 34.0 for women who had miscarried;

this proportion is 2.9 times that of pregnant women with children (95% CI = 1.5, 5.1) and 2.3 times that of community women (95% CI = 1.5, 3.3) in adjusted analyses.

Length of Gestation

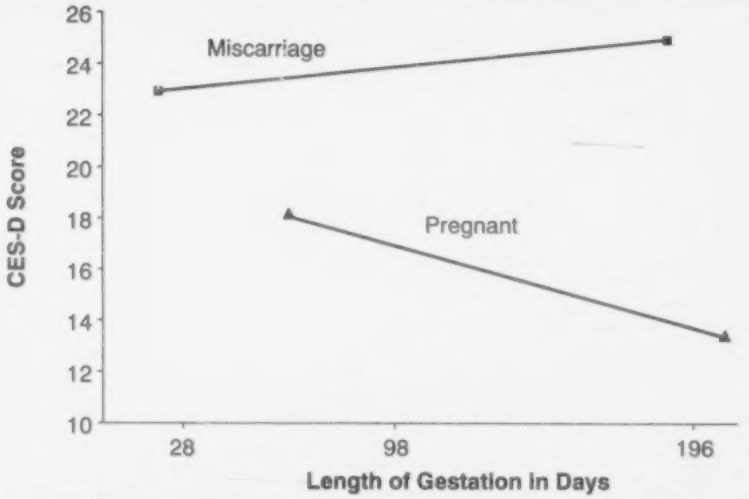
The association of length of gestation with depressive symptoms differs between the miscarriage and pregnant cohorts. In the pregnant cohort, observed symptom means declined with gestational advance (Table 2). In the miscarriage cohort, depressive symptoms were not associated with length of gestation; that is, women with early and late miscarriages had equally high levels of depressive symptoms. Hence, given the decline in symptom levels expected at later stages of an uninterrupted pregnancy, miscarriage is seen to exert a greater effect on women at later points in gestation (Figure 2). (This pattern of results persisted even after we restricted the analysis to gestational periods characterized by greater overlap between the two cohorts.)

Attitude toward the Pregnancy

The association of depressive symptoms with attitude toward pregnancy also varied between the miscarriage and pregnant cohorts. In the pregnant cohort, depressive symptom levels were higher in women with unwanted pregnancies; in the miscarriage cohort, depressive symptom levels were unrelated to the woman's attitude toward the pregnancy (Table 2, Figure 3). Hence, when pregnant women are used as the standard, miscarriage has a greater impact on women with wanted pregnancies than on women with unwanted pregnancies. However, these effects of attitude do not account for the pattern of results pertaining to number of children, described earlier, since that pattern persists when the analysis is restricted to women with wanted pregnancies.

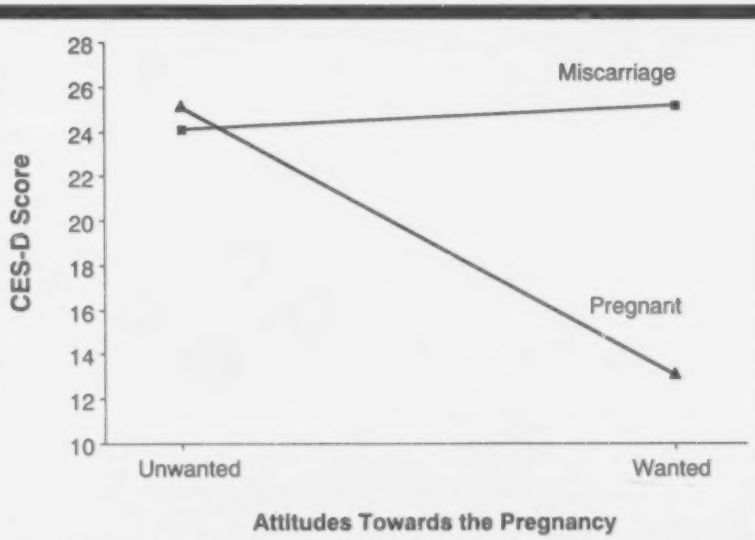
Prior Reproductive Loss, Maternal Age, Marital and Socioeconomic Status, and Religion

Depressive symptom levels were not raised in women with prior reproductive loss or in older women (aged 35 and older) within any study cohort in either uncontrolled (Table 2) or controlled analyses. Hence, miscarriage does not appear to exert a disproportionately greater effect on women with prior reproductive loss or on older women. These results did not change in analyses confined to nulliparous women. The effect of miscarriage on depressive symptoms also did not vary by marital status.



Note. CES-D = Center for Epidemiologic Studies Depression Scale. The slope of each line (*b*) represents the unstandardized regression coefficient for the term for length of gestation in days, from within-cohort least squares multiple regression equations. In the pregnant cohort, $b = -0.04$ per day (95% CI = −0.09, 0.008), $P < .11$; in the miscarriage cohort, $b = .02$ per day (95% CI = −0.03, 0.06), $P < .46$. The interaction term (cohort by length of gestation) is significant at $P < .08$.

FIGURE 2—Length of gestation and adjusted CES-D scores in miscarriage and pregnant cohorts.



Note. CES-D = Center for Epidemiologic Studies Depression Scale. The slope of each line (*b*) represents the unstandardized regression coefficient for the term for pregnancy attitude, from within-cohort least squares multiple regression equations. In the pregnant cohort, $b = -1.05$ (95% CI = −1.5, −0.6), $P < .00001$; in the miscarriage cohort, $b = 0.07$ (95% CI = −0.6, 0.7), $P < .82$. The interaction term (cohort by attitude) is significant at $P < .009$.

FIGURE 3—Attitude toward the pregnancy and adjusted CES-D scores in the miscarriage and pregnant cohorts.

Depressive Symptoms vs Somatic Complaints

The depressive symptoms reported by subjects in our study might have consisted largely of somatic complaints and affective disturbances arising from the physical sequelae of the miscarriage (or of the pregnancy). To evaluate this possibility, we repeated all of the preceding analyses after

first removing the somatic items (e.g., appetite and sleep disturbance) from the CES–D and then entering the summed score of the deleted items as a covariate in the regression equations. The preceding patterns persisted. Furthermore, although one third of the women who had miscarried had been hospitalized overnight and another third had been hospitalized for two or more nights, hospital stay was unassociated with symptom levels. Women who had had a dilation and curettage (approximately 85%) and those who had not also did not differ on level of depressive symptoms.

Discussion

Depressive symptoms were increased substantially in the early weeks after loss in this study sample. Symptom means in the miscarriage cohort approximated levels reported for heterogeneous samples of psychiatric inpatients.[22] The proportion of women who were highly symptomatic was 3.4 and 4.3 times greater in the miscarriage cohort than in the pregnant and community cohorts, respectively.

Childless women who had miscarried proved especially vulnerable to depressive symptoms. For example, the proportion highly symptomatic was 11 times higher among childless women who had miscarried than among childless community women. By contrast, the presence of several children is entirely protective. Several prior investigations of miscarriage, albeit not all,[9] have also reported lower symptom levels with increasing numbers of children.[11,15,31] However, since these studies lacked comparison groups they did not disclose the more striking finding that women with several children who miscarry do not exhibit significantly higher symptom levels than women with children who have not experienced a recent reproductive loss.

The apparent absence of a depressive effect of miscarriage on women with several children contradicts a large body of research linking life events involving loss to increases in depressive symptoms.[32] Recent stress research has focused on factors that buffer individuals from the pathogenic effects of negative life events, with much attention accorded to social supports.[33] For a woman who miscarries, the presence of living children may afford psychological support indirectly, by representing evidence of reproductive success in the past. This finding merits further investigation.

We found women with early and late miscarriages to be equally depressed, as has been noted in some other studies.[7,12,13] However, compared with pregnant women of similar gestational lengths, women with late loss apparently experienced a greater rise in depressive symptoms than women with earlier loss. This finding of a greater effect of miscarriage with length of gestation is consistent with the notion that maternal attachment to the unborn child progresses as the pregnancy advances and that the impact of loss corresponds to the strength of the preceding attachment.[31,34]

Again, when pregnant women are used as a reference group, loss of a wanted pregnancy is associated with a marked increase in symptom levels, whereas loss of an unwanted pregnancy is not. Women with unwanted pregnancies already have elevated symptoms and therefore apparently experience no further increase at the time of miscarriage. However, women losing wanted and unwanted pregnancies are equally depressed, as reported elsewhere.[8,15,31] Both situations warrant clinical and public health concern, as do pregnant women carrying unwanted conceptions.

Women with a history of prior reproductive loss, consisting predominantly of miscarriages, were not affected more strongly by their miscarriages than were women without prior loss. Previous studies of miscarriage[11,13,14,31] found no association between prior loss and current symptoms in their study cohorts. With one exception,[35] findings from previous investigations of perinatal death concur.[16,36–39] Our study findings also obtained in analyses restricted to nulliparous subjects.

With the current trend in industrialized societies of women postponing childbearing until later years, the effect of miscarriage on older women deserves special mention. Our finding that older women in the miscarriage cohort were not more depressed than younger women agrees with earlier results from research on women who had miscarried[10,11,13,14,31] and on women experiencing perinatal death.[16,36–37,39] Restriction of our analyses to nulliparous women did not alter these findings.

This study demonstrates for the first time that miscarriage powerfully influences maternal psychiatric status in the first few weeks after loss. Physicians in general practice, as well as gynecologists, should be aware both that nulliparous women may be in special need of attention following a miscarriage and that women experiencing even very early loss or the loss of an ostensibly unwanted pregnancy may exhibit markedly high levels of depressive symptoms. The possible persistence of these effects among certain subgroups of women awaits future investigation. □

Trends in Obstetric Operative Procedures, 1980 to 1987

S. Christine Zahniser, RN, MPH, Juliette S. Kendrick, MD, Adele L. Franks, MD, and Audrey F. Saftlas, PhD

ABSTRACT

Objectives. Increasing rates of cesarean deliveries have received widespread attention in recent years, as concern in the United States about unnecessary surgical procedures has increased. However, little information has been published on the national trends of other operative obstetric procedures occurring during deliveries.

Methods. We analyzed data from the National Hospital Discharge Survey to examine trends in the use of forceps, vacuum extraction, and cesarean section from 1980 through 1987.

Results. The rate of cesarean sections increased by 48%, while the rate of forceps procedures declined by 43%. Although the risk of cesarean section was significantly increased for older women, the risk of forceps and vacuum extraction procedures did not vary by age. Women with private insurance were significantly more likely to receive a cesarean section (rate ratio [RR] = 1.2), forceps procedure (RR = 1.7), and vacuum extraction procedure (RR = 1.8) than were women without private insurance.

Conclusions. As pressure mounts to decrease the national cesarean section rate from 24% to 15% by the year 2000, attention should also be given to surveillance of other operative delivery procedures. (*Am J Public Health.* 1992;82:1340–1344)

Introduction

Increasing rates of cesarean deliveries have received widespread attention in recent years, as concern in the United States about unnecessary surgical procedures has increased. In 1987, cesarean deliveries became the most frequently performed surgical procedure among women of childbearing years.[1] Some researchers have hypothesized that this increase in cesarean sections is the result of a decrease in the use of forceps.[2] However, limited information has been published on the national trends of other operative obstetric procedures occurring during deliveries.[3] Here, we examine US trends in the use of forceps, vacuum extraction, and cesarean section over an 8-year period. In addition, we present the demographic characteristics of women most likely to receive these interventions.

Methods

We analyzed data from the National Hospital Discharge Survey, conducted by the National Center for Health Statistics. Each year, a representative sample of discharges is selected from approximately 400 short-term–stay, nonfederal hospitals throughout the United States.[4] About 200 000 abstracts of medical records are sampled annually. Data are transcribed from the face sheet of the medical record to the National Hospital Discharge Survey abstract form. Abstracted items include demographic characteristics of the patient, administrative information, expected sources of payment, up to seven discharge diagnoses, and up to four procedures. Coding is performed according to the *International Classification of Diseases,* 9th revision, Clinical Modification (ICD-9-CM).[5]

We restricted our analysis to women hospitalized for a delivery (ICD-9-CM codes V27.0 through V27.9) from 1980 through 1987. The obstetric procedures we analyzed included the use of forceps (ICD-9-CM codes 72.0 through 72.49, 72.51, 72.53, 72.6, 73.3), vacuum extraction (72.7), and cesarean sections (74.0 through 74.29, 74.4, 74.99). For each delivery, we selected only one operative procedure code, even if more were present. For example, in the many cases in which both low forceps use (72.0) and forceps rotation of the fetal head (72.4) were recorded, we analyzed this combination as one forceps procedure.

We classified the mother's race as "White" or "Black and other minorities." Insurance status was established on the basis of information collected from patients at admission to the hospital. Women whose expected source of payment included any type of private or commercial insurance were reported as having "private insurance." Women who reported self-payment or government payment, including Medicaid/Medicare, were considered to have "no private in-

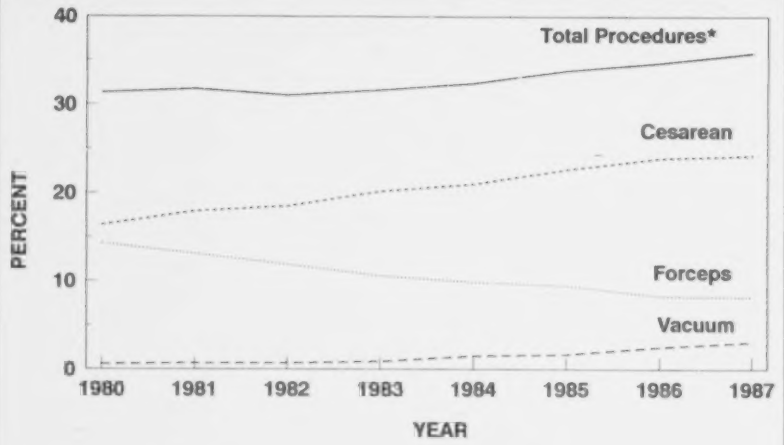
surance." Women in the "other" payment group, which consisted of those in the "workman's compensation," "no charge," or "other" payment categories, represented less than 5% of the sample and were excluded from the analysis of insurance data. Rate ratio analyses of the 1987 deliveries were conducted to identify women at increased risk of having the various procedures.

We used the computer program SESUDAAN (Research Triangle Institute, Research Triangle Park, NC) to calculate rates and their corresponding standard errors,[6] and we took into account the complex multistage sampling design of the National Hospital Discharge Survey. We used the Taylor series expansion with the logit transformation to calculate 95% confidence intervals on rate ratios.[7] Weighted linear regression was used to test for linear trend in the rates of various procedures over the 8-year study period.[8] Rates and rate ratios are provided only for procedures with 5000 or more discharges; estimates of less than 5000 in the National Hospital Discharge Survey are considered statistically unreliable[3] since they are based on fewer than 30 records. We calculated crude and adjusted rates of cesarean section, forceps, and vacuum extraction procedures for 1987. Because the age- and race-adjusted rates were similar to the crude rates, we present only the crude rates here.



* Total procedures include cesarean section, forceps, and vacuum extraction

Results

General Trends

The number of operative delivery procedures, including cesarean sections, forceps, and vacuum extraction procedures, increased from 1.2 million in 1980 to 1.4 million in 1987, affecting 35.8% of all deliveries in 1987, compared with 31.3% in 1980 (Figure 1). Between 1980 and 1987, cesarean sections increased by 48% (from 617 000 to 949 000), whereas forceps procedures declined by 43% (from 539 000 to 320 000). In comparison, vacuum extraction procedures increased from 0.6% to 3.3% of all deliveries (from 22 000 to 122 000); most of this increase occurred after 1983.

[a]Women with unknown race were excluded (13.5% of those with private insurance and 14.1% of those without private insurance).

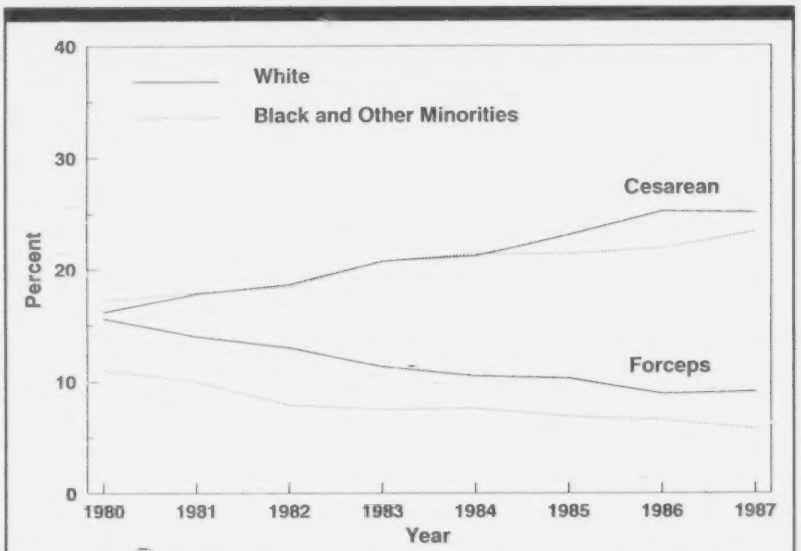

FIGURE 2—Rate of US cesarean sections and forceps procedures, by race, 1980 to 1987, National Hospital Discharge Survey, National Center for Health Statistics, Hyattsville, Md.

Length of Stay

Despite the increase in the percentage of all deliveries associated with an operative procedure, the mean length of hospital stay for all deliveries decreased from 3.8 days in 1980 to 3.1 days in 1987 (test for linear trend, $P = .0001$). During the same period, the mean length of hospital stay for cesarean section deliveries declined from 6.5 to 4.8 days (test for linear trend, $P = .0001$); for forceps deliveries, it decreased from 3.5 to 2.8 days (test for linear trend, $P = .0001$); and for vacuum extractions, it declined from 3.2 to 2.7 days (test for linear trend, $P = .002$).

Age

The risk of having a cesarean section increased with the increasing age of the mother. Women 35 years of age and older were 30% more likely to receive a cesarean section than were women 20 through 34 years of age (Table 1). In contrast, there were no significant differences in the rates of forceps or vacuum extraction procedures among women of different ages. From 1980 to 1987, the rate of cesarean sections increased significantly in each age group (test for linear trend, $P < .002$ in each age group).

Race

Since 1980, rates for cesarean sections have increased 55% among Whites and 36% among Black and other minority women (test for linear trend, $P = .0001$ for each racial group) (Figure 2). Forceps procedures declined 41% among White women and 46% among Black and other minority women (test for linear trend, $P = .0001$ for White women and $P = .0008$ for Black and other minority women). In 1987, White women were 60% more likely to have a forceps delivery than were Black and other minority women (Table 1).

Insurance Status

For each year in the study period, insured women had higher rates of cesarean sections, forceps procedures, and vacuum extraction procedures than did uninsured women. In 1987, women with private insurance were 20% more likely to have a cesarean section, 70% more likely to have a delivery by forceps, and 80% more likely to have a vacuum extraction procedure than women without private insurance (Table 1). To further investigate the relationship between operative delivery procedures and race, we stratified by insurance status (Table 2). Within each insurance category, the rate of each procedure was not significantly different between the two racial groups.

Geographic Region

The rate of specific intervention procedures differed slightly by geographic region within the United States (Table 1). For example, women in the South were more than twice as likely to have a forceps delivery as women in the West, and women in the Northeast were 20% more likely to be delivered by cesarean section than were women in the West. Although women in the West had the highest rate of vacuum extraction procedures, this rate was not statistically different from that of other regions.

Discussion

In 1987, an operative procedure was performed on more than a third of all women in delivery. Although the rate of cesarean sections increased by 48% between 1980 and 1987, the rate of forceps

procedures declined by 43%. During this same period, Kozak reported a 42% increase in the rates of a variety of surgical and nonsurgical procedures associated with US hospital deliveries.[9] Cesarean sections, repair of obstetric lacerations, artificial rupture of membranes, and vacuum extraction accounted for more than half the increased number of delivery procedures. Of the 11 procedures Kozak evaluated, only the use of forceps declined.

Our analysis of procedure rates by maternal age showed that older women were significantly more likely to receive a cesarean section than were younger women—a finding supported by previous studies,[2,10,11] even when researchers controlled for other risk factors such as preexisting hypertension and diabetes.[12] In contrast, the rates of forceps and vacuum extraction procedures did not increase among older women. Obstetricians may apply different criteria when choosing a method of delivery for older women, whom they consider to be at high risk.[12] This may explain why the rate of forceps procedures was slightly lower among women 35 years of age and older in our study.

Disparities in access to and receipt of health care services for Blacks have been previously reported.[13] Other studies have looked at the difference in cesarean section rates by race and ethnicity, often in combination with socioeconomic status or payment source.[14,15] Gould et al. controlled for family income and found no significant difference in cesarean rates between non-Hispanic White and Black women.[15] They did find significantly higher rates among women of higher income levels regardless of race, however. We found that White women had the same risk of receiving a cesarean section as Black and other minority women, while the risk of forceps procedures was significantly higher for White women. When we stratified by insurance status, the racial difference was no longer seen for any of the delivery procedures.

Private patients and those with private insurance tend to have the highest rates of cesarean sections, whereas clinic and uninsured patients tend to have the lowest rates, regardless of risk status.[14,16–19] Women who obtain services from a health maintenance organization tend to have intermediate cesarean rates.[14] Other surgical procedures, including hysterectomy and tonsillectomy, also are performed more frequently when the physician is reimbursed on a fee-for-service basis.[20] Our data indicate that cesarean sections are 20% more likely to occur among insured women than they are among women without private insurance. Moreover, forceps and vacuum extraction procedures are 70% to 80% more likely to be performed among women with private insurance than among those without private insurance.

Geographic variations in health care practices[19,21–23] and higher cesarean section rates in the Northeast and South have been previously reported, but information on the geographic variation in forceps and vacuum extraction procedures has not previously been published. We found the rate of forceps procedures to be significantly greater in the South.

Some researchers have suggested that the increase in cesarean sections is partly responsible for the decline in forceps procedures.[2] Our findings are consistent with this hypothesis, although we cannot test its validity with the National Hospital Discharge Survey data. Information about additional factors that can influence the rates of cesarean and forceps procedures (e.g., parity, fetal conditions during labor, birthweight) is not available within this data set. In the near future, however, additional information will be available to examine indications and outcomes of operative delivery procedures. The revised US Standard Certificate of Live Birth was implemented by all states in 1991, and it contains a question on method of delivery.[24] This will facilitate the evaluation of operative delivery procedures by birthweight, gestational age, Apgar score, and many abnormal conditions of the newborn.

The Healthy People 2000 Objectives call for decreasing the national cesarean section rate from 24% to no more than 15% of all deliveries (the objectives do not address other operative delivery procedures).[25] Numerous strategies have been proposed to lower the cesarean section rate in the United States.[23,26] For example, in two programs that reduced cesarean section rates to about 11% (from 18% and 28%),[27,28] a comprehensive system of peer review was established, and all cesarean sections were discussed at staff conferences. Standardized protocols and required second opinions have also been found to be effective.[23,27,28] The protocol of Myers and Gleicher led to a decline in the rate of cesarean deliveries (from 17.5% in 1985 to 11.5% in 1987) and in the rate of operative vaginal deliveries (from 10.4% in 1985 to 4.3% in 1987).[27] Sanchez-Ramos and colleagues reported that their rate of operative vaginal deliveries remained stable as the rate of cesarean sections decreased (from 27.5% in 1986 to 10.5% in 1989).[28] In 1989, however, their rate of operative vaginal procedures was 18.5%, far greater than the national rate.

As the pressure mounts to reduce the number of cesarean sections performed in US hospitals, we also should focus our attention on the surveillance of other operative delivery procedures. Prospective studies of maternal and infant characteristics and outcomes are needed to help us determine which procedures can produce the best outcomes for mothers and infants. □

Changes in Mammography Use: Economic, Need, and Service Factors

ABSTRACT

Objectives. **The purpose of this study was to document changes in mammography use between 1987 and 1990 and assess the relationship of use to selected economic, need, and health system factors.**

Methods. **Independent random-digit-dialed telephone surveys of women between 52 and 75 years of age were conducted.**

Results. **Between 1987 and 1990, the proportion of women who had had a mammogram in the past year increased from 31% to 51%. Though income was significantly related to overall patterns of use, it was not associated with recent mammogram use in 1990. Women with a family history of breast cancer reported greater use at both times, as did women who reported having a regular physician (particularly a gynecologist or internist). When all other variables were controlled for, women were over nine times more likely to have had multiple and recent mammograms in 1990 than in 1987.**

Conclusions. **Mammography use dramatically increased between 1987 and 1990. There were strong relationships between the type of regular physician and mammography screening and between economic and personal history and repeated and recent mammography use. (*Am J Public Health.* 1992;82:1345–1351)**

Introduction

Breast cancer continues to be a prominent women's health problem, representing 28% of all female cancers.[1] Since reductions in mortality depend on increasing the adoption of early detection methods by physicians and by women, numerous professional organizations have endorsed screening guidelines for periodic clinical breast examinations and mammography.[2] If the Year 2000 Health Goals for the Nation are to be achieved, a better understanding of factors related to screening services use is needed.[3]

In this study we document changes in mammography utilization over a 3-year period and investigate the relationship of selected economic, need, and health system factors to mammography screening utilization to determine which subgroups of women are being screened.

Methods

Study Subjects and Data Collection

Independent random-digit-dialed surveys of English-speaking women between 52 and 75 years of age who had never had breast cancer were conducted in two Massachusetts urban areas comprising six towns. The surveys were conducted in the fall of 1987 (n = 929) and the fall of 1990 (n = 674) as part of a 3-year demonstration project, sponsored by the National Cancer Institute (NCI), designed to increase breast cancer screening.[4] The study sample was drawn from the demonstration and comparison urban areas. The interviews, averaging 17 minutes in length, were conducted during day and evening hours, with a minimum of 10 call-backs at varying times. A refusal conversion call procedure was used, and response rates of 75.3% in 1987 and 73.9% in 1990 were achieved. The 52-year age minimum was based on professional guidelines recommending annual screening for women aged 50 years and older. Therefore, a 52-year-old woman could have adhered to the recommendation at least twice.

Study Variables

The dependent variable, mammography utilization, was defined with four categories: (1) no mammogram (never had one); (2) previous user (had had one or more mammograms, but none in the previous 12 months); (3) recent adopter (had had only one mammogram, which had occurred in the previous 12 months); and (4) repeat recent user (had had two or more mammograms, including one in the previous 12 months). This variable was designed to provide a better understanding of factors influencing periodic as well as recent utilization. For a subsequent analysis, the categories were collapsed (1 plus 2; 3 plus 4) to form a binary dependent variable, defined as having had a mammogram in the previous 12 months or not. Because of missing data, the 1987 and 1990 samples consisted of 838 and 601 women, respectively.

In the selection of study variables, which was guided by previous work,[5–7] we focused on three groups of factors

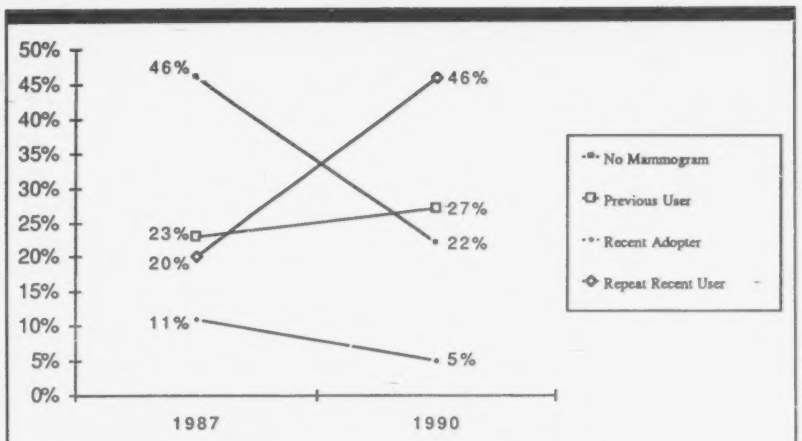

FIGURE 1—Percentages of women using mammograms, by pattern of use.

(economic, need, and health system enabling factors) and their relationships to screening. Economic factors included measures of income, education, and employment. Personal health need factors, such as family history of breast cancer, personal history of breast symptoms, and age, may influence use of screening by influencing women's personal perception of risk, their physicians' attention to screening recommendations, or both. Access to and interaction with health providers may facilitate or hinder mammography use. A physician's advice that a client obtain a mammogram was one health system enabling factor investigated in this study; others included having insurance coverage, having a regular physician, and having had a clinical breast exam in the past year.

Analysis

A univariate examination of the relationship between study variables and mammography use was performed for each survey. To better control for potential confounding, variables significant at the .15 level in either survey were selected as candidates for multivariate modeling. A polytomous logistic regression model was used to assess the joint effects of the variables.[8] Likelihood ratio tests reduced the model to that subset of variables significant at the .10 alpha level in either survey. An indicator variable for city was included in all models to control for intervention effect. To check for possible shifts in effects between survey waves, a combined model was fit, and interactions between time and study variables were tested by means of likelihood ratio tests. None were significant at the 5% level. The adequacy of the polytomous logistic regression model was assessed by applying logistic regression diagnostics to equivalent separate sample binary logistic regression models. In the second phase of the analysis, models employing the binary dependent variable (mammogram in the past 12 months or not) were fit to the data.

Results

Mammography Utilization

The pattern of mammography use was significantly related to study period ($\chi^2 = 151.2$; $P < .0001$, $df = 3$). The proportion of women who had had a mammogram in the past 12 months (the recent adopters plus the repeat recent users) increased from 31% in 1987 to 51% in 1990 (Figure 1); a corresponding decrease occurred in the proportion of women who had never had a mammogram, from 46% to 22%. Both shifts were statistically significant ($P < .0001$). The proportion of previous users increased from 23% to 27%; the proportion of recent adopters decreased from 11% to 5%; and the proportion of repeat recent users increased from 20% to 46%. Only the latter two shifts were statistically significant ($P \leq .0002$).

Relationship of Study Variables to Mammography Use

Economic variables. The relationship of employment status to screening use was of borderline significance in 1987, but not in 1990 (Table 1). In 1987, unemployed women were somewhat more likely to have never had a mammogram, whereas employed women were slightly more likely to be previous users. Education and income level were significantly related to utilization at both times. Women with less than a high school education were most likely to have never had a mammogram, whereas college graduates were most likely to report the highest utilization in both surveys. Women with total household incomes of $15 000 or less were most likely to have never had a mammogram and least likely to be previous users or recent users. More women in the lower income groups reported having had a recent mammogram in 1990 than in 1987, but their rates were still lower than those of high-income women.

Need variables. Women with a family history of breast cancer were significantly more likely to have had screening in 1987, but not in 1990 (Table 1). Women with a personal history of breast symptoms or problems were significantly more likely to be previous users and repeat recent users in both surveys. In 1987, women 65 years of age and older were more likely to have never had a mammogram, but were about as likely to have had one in the past year as younger women. By 1990, the two age groups had very similar patterns of use.

Health system enabling variables. In both 1987 and 1990, having either an internist or a gynecologist as a regular physician was related to ever having had a mammogram, as well as to being a repeat recent user (Table 1). In both surveys, women who reported being advised by a physician to have a mammogram had higher levels of use. Having had a recent clinical breast examination was significantly and consistently associated with ever having had a mammogram and with being a repeat recent user.

Insurance coverage was significantly related to mammography utilization at both times (Table 1). However, analyses of the relationship between insurance coverage and screening utilization should be interpreted with caution. Because some women had multiple sources of insurance, it was not possible to determine which plan actually provided coverage. In addition, coverage may change annually, so comparing mammography use over time with current coverage is of dubious validity. Therefore, we investigated the relationship of insurance coverage to mammogram use in the previous year (recent adopters and repeat recent users combined). Though this relationship was of borderline significance in 1987 and nonsignificant in 1990, certain trends are noteworthy (Figure 2). Women with no insurance were least likely to have had a mammogram in the past year in both 1987

and 1990. Women with entitlements only or entitlements plus other coverage did substantially better in 1990 than in 1987. In both years, women with health maintenance organization coverage were more likely than women in any other coverage group to have had a mammogram in the past year.

Aside from the significant relationships of the independent variables with utilization at each time point, notable changes occurred over time. For example, more women were advised by their physicians to have a mammogram in 1990 than in 1987 (81% vs 59%). Although the proportion of women who had had a clinical breast exam in the previous year did not change (59% in 1987 and 60% in 1990),

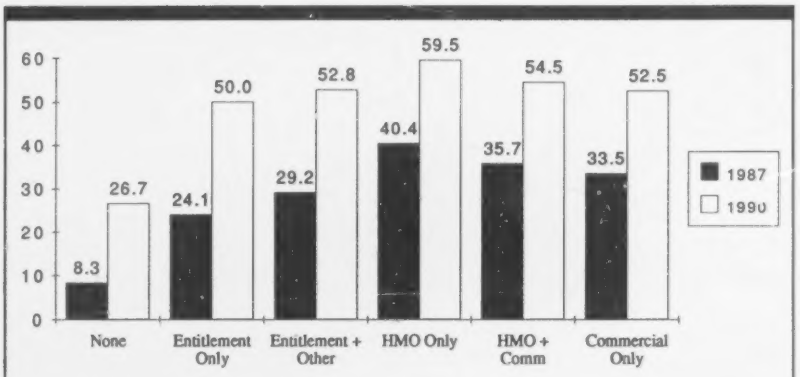

FIGURE 2—Percentages of women having a mammogram in the previous 12 months, by insurance coverage.

more women who had had such an exam reported having had a mammogram in 1990 (72%) than in 1987 (49%).

Multivariate Analyses

Multivariate analysis was used to investigate the relationship of specific variables to utilization while controlling for the effects of others. The variable "physician advised patient to get a mammogram" was not included because of its high correlation with the dependent variable. Insurance coverage was omitted because of its lack of validity with respect to utilization in other than the past year. The fitted logistic regression models are presented in Tables 2 and 3 in the form of odds ratios, obtained by exponentiating the estimated coefficients, and confidence intervals for the odds ratios.

In Table 2, odds ratios are given that compare the referent group, women who had never had a mammogram, with the three user groups: previous users, recent adopters, and repeat recent users. Consequently, for each dichotomous variable in Table 2, there are three odds ratios. For the variable "specialty of regular physician," four sets of odds ratios are given, one for each physician specialty compared with having no regular physician. The income variable was treated as continuous and the odds ratio for an increase of $5000 is presented.

The first column of odds ratios in Table 2 reports the results of the model for the 1987 survey. When other important variables were controlled for, economic factors retained their significance. Employed women were less likely than unemployed women to be repeat recent users. Women with at least a high school education were more likely than women with less than a high school education to be previous users. Higher income increased the likelihood of a woman's being a repeat recent user.

With regard to need factors, women who reported a family history of breast cancer were approximately three times more likely than others to be recent adopters or repeat recent users in 1987. Women who had had breast problems were more than six times as likely as others to have ever had more than one mammogram. The likelihood that a woman who had had symptoms was a recent adopter, though not significant, was nearly twice as high as the likelihood that she had never had a mammogram. Women younger than 65 years of age were twice as likely as older women to be repeat recent users.

With regard to health system enabling factors, women whose regular physician was an internist or gynecologist reported greater use than did women with no regular physician. In addition, they were almost eight times more likely than women who regularly visited a general practitioner or family physician to be repeat recent users. If a woman had had a clinical breast exam in the past 12 months, she was 12 to 18 times more likely to have had a recent mammogram. Women in the demonstration city area were less likely to report previous use than were those in the comparison city area; recent use was similar.

The same model fit to the 1990 survey data is displayed in the center columns of Table 2. Variables significant in this model included education, previous breast problems, specialty of regular physician, and recency of clinical breast exam. The overall relationships between mammography use and having had a breast problem and recency of clinical breast exam were the same as in 1987, although the odds ratios changed somewhat. Women were far more likely to be recent adopters if they had a regular physician (21 to 22 times more likely if the physician was a gynecologist or internist, and almost 9 times more likely if the physician was a general practitioner or family physician). Women were also more likely to be repeat recent users if they reported having a regular physician (from 2 to 17 times more likely, depending on the specialty of the regular physician).

In the next stage of analysis (final columns of Table 2), we fit the same model to the combined survey data, including an indicator variable for time. In the combined model, when other significant variables were controlled for, two economic factors achieved statistical significance. Women with more than a high school education were more than twice as likely to be repeat recent users, and a $5000 increase in income increased the likelihood that a woman would be a repeat recent user. With respect to need factors, women with a family history of breast cancer were twice as likely as other women to be repeat recent users; those with a history of breast problems were more than eight times as likely to be repeat recent users. Age was not significantly related to use when the influence of all other variables was controlled. Among the health system enabling factors, specialty of regular physician continued to be highly significant. Women whose regular physicians were gynecologists or internists were more likely to have ever had a mammogram. When all other variables were controlled for, women were more than nine times as likely to be repeat recent users in 1990 than in 1987.

Because several national reports have focused on the number of women who have had mammograms in the 12 months prior to study,[4,9] models were fit to the dichotomous outcome variable (having had a mammogram in the past 12 months or not). The models for 1987, for 1990, and combined over time are presented in Table 3. Economic variables were not significant, except for income in 1987 and education in 1990. Having had previous breast problems was related to use in both 1987 and 1990, whereas having a family history of breast cancer was related in 1987 only; age was not related. Having as a regular physician a gynecologist (or an internist in the 1990 and combined-time models) and having had a clinical breast exam in the past 12 months were related to increased likelihood of recent use. A model that included insurance rather than income yielded similar results.

TABLE 2—Estimated Odds Ratios and 95% Confidence Intervals (CI) for Mammography Utilization in 1987, in 1990, and Combined over Time

Effect	Mammography Utilization (vs None)	1987		1990		Combined

Discussion

The results of this study support recently published data that document improvements in the proportion of women who have had a mammogram in the year prior to study.[9] In addition, this study documents an increase in the proportion of women who have been screened recently among those who have had mammograms in the past (20% in 1987 to 46% in 1990). The challenge will be to promote regular screening by new adopters, to continue to encourage the substantial proportion (approximately 25%; see Figure 1) of previous (but not recent) users to again participate in screening, and to motivate the hard-to-reach 22% who have never been screened. One limitation of this study is the lack of representation of minority and non-English-speaking women; more than 90% of each sample was White. The study is also limited by the usual biases of random-digit-dialed surveys: only women with telephones could participate and the data were self-reported.

Among the economic factors, income was significantly related to repeat recent

mammography use in 1987 and in the combined model (Table 2); however, income was not significantly related to recent mammography use in 1990 (Table 3). This change may be due, in part, to the fact that more women with entitlements were being screened in 1990 (Figure 2).

With respect to need factors, having had breast problems was significant in all three models, whereas having a family history of breast cancer was significant only in the 1987 and combined models. Both factors were also significantly related to recent mammography use in 1987 and in the combined model (Table 3). It could be hypothesized that clinicians in 1987 were more likely to advise screening for these women because of their health history, but more recently, all women have been advised to have regular mammograms. It is not surprising that a history of breast symptoms or problems is independently related to mammography use. In both 1987 and 1990, 17% of the women reported that they had had their most recent mammogram because they had had a breast problem, rather than as part of a regular checkup. It may be that these women misunderstood why the mammogram was recommended. For example, considerable anecdotal evidence suggests that mammograms are ordered to rule out problems in order to secure insurance coverage.

The bivariate relationship of age and family history to increased use in 1987 and 1990, coupled with increases in use over time, supports the notion that screening of all women is increasingly being encouraged. The relationship of income and education to use supports the recommendation that special attention be given to the underserved, that is, women with lower incomes and less education. In this regard, it is encouraging that in 1990 more women with entitlements only and more uninsured women were receiving care. However, the fact that more elderly women were being screened provides additional evidence that factors other than income influence mammography use.[10-12]

With respect to health system enabling factors, this investigation demonstrates the continued profound relationships between having a regular physician and mammography use and between physician specialty and mammography use that have been documented in earlier studies.[4,13-15] Although having a gynecologist as a regular physician continues to be important, women reporting internists as regular physicians have improved their use of mammography in recent years. Since women who indicated that their regular physician was a general practitioner reported lower use, continuing education programs might target those physicians.[16,17] In addition, public education programs should consider encouraging women themselves to initiate discussions of mammography with their physicians.

It is also not surprising that having had a clinical breast exam in the past 12 months was related to greater use. Apparently, a woman who undergoes a physical is more likely to be encouraged to have a mammogram. However, there continues to be considerable "missed referral opportunity"[4]: 28% of the women who had had a clinical breast exam in the previous year did not go on to get a mammogram (Table 1). In addition, many women reported not having had a clinical breast exam in the previous year (Table 1). Attention to both mammography and clinical breast exams is therefore important. Providers should continue to initiate discussion of screening and public education programs should continue to emphasize the importance of periodic checkups that include clinical breast exams and mammogram referrals, particularly for women of lower educational levels. □

Current Cigarette Smoking and Risk of Acute Pelvic Inflammatory Disease

Delia Scholes, PhD, Janet R. Daling, PhD, and Andy S. Stergachis, PhD

ABSTRACT

Objectives. Further information is needed on modifiable factors associated with the occurrence of acute pelvic inflammatory disease (PID). Cigarette smoking has been implicated as a risk factor for PID sequelae, but the association between smoking and PID has yet to be fully examined.

Methods. We conducted a population-based case-control study to evaluate smoking as a risk factor for acute PID. The case patients (n = 131) were women health maintenance organization (HMO) enrollees between the ages of 18 and 40 years who were treated for a first episode of PID. The control patients (n = 294) were randomly selected from the HMO enrollment files.

Results. Relative to never smokers, current smokers were at increased risk of PID. Women who smoked 10 or more cigarettes per day had a higher risk than did those who smoked less. Available data indicate that smoking status is not serving as a marker for uncontrolled confounding by lifestyle factors.

Conclusions. Our study results suggest that smoking represents a modifiable risk factor for acute PID. (*Am J Public Health.* 1992;82:1352–1355)

Introduction

Cigarette smoking has been implicated as a risk factor for ectopic pregnancy[1–5] and tubal infertility.[6] One way in which smoking may affect both of these outcomes is by increasing a woman's risk for pelvic inflammatory disease (PID), a severe upper genital tract infection that may result in scarring and obstruction of the fallopian tubes. Although one study[7] found an increased risk for smokers, the relationship between smoking and PID has yet to be fully examined. We evaluated this association in a population-based series of cases and controls from the Group Health Cooperative of Puget Sound.

Methods

The case patients consisted of women aged 18 to 40 years who experienced their first episode of acute PID between September 1984 and November 1985. The Group Health Cooperative automated hospital information system was used to select inpatients who had received a primary discharge diagnosis of acute PID or salpingitis. The automated pharmacy database was used to select potential ambulatory care PID cases. Medical records of women who were prescribed either doxycycline or a high-dose regimen of tetracycline[8] were reviewed for a diagnosis of PID. All medical records were reviewed for the presence of three clinical inclusion criteria: abdominal pain of 1 month's duration or less, cervical motion or uterine tenderness, and adnexal tenderness. Patients were included only if all three symptoms and signs were noted.

The control patients were part of a control group for a concurrent population-based study of ectopic pregnancy conducted at Group Health Cooperative. These women were selected randomly from the enrollment files. Control patients with reference dates (dates assigned to approximate the date of conception of the assigned case) between January 1984 and August 1986 were selected randomly from the enrollment files and matched to the women with ectopic pregnancies on age and county of residence.

The following inclusion criteria were applied to all potential research subjects: resident of King County; no prior history of PID; sexually active within the preceding year; no prior hysterectomy or bilateral salpingo-oophorectomy; not pregnant; no pelvic surgery or uterine instrumentation within the preceding 6 weeks; no vasectomized partner at reference date.

An in-person interview was used to collect information on cigarette smoking status at diagnosis/reference date, duration and amount smoked, and, for former smokers, length of time since quitting. Similar information was obtained on respondents' partners where applicable.

Unconditional logistic regression[9] was used to assess the role of smoking as

a risk factor while controlling for the confounding effects of age, race, gravidity, and number of sexual partners in the year prior to reference date. Risk estimates of smoking in relation to PID were not substantially altered when income, education, marital status, presence and type of contraception at reference date, and recent douching were added to the model.

Results

We interviewed 131 (72.4%) of the 181 case patients identified as eligible. Twelve percent of the 131 were hospitalized. Of the 428 women identified as potential controls, 314 (73.4%) were interviewed. We excluded 20 control patients with a history of PID.

Case patients were more likely to be younger, to have lower incomes and less education, to be non-White, to have been previously pregnant, and to have had more than one sex partner in the previous year (Table 1). They were less likely to be married at reference date.

More case patients (43.5%) than control patients (25.6%) were current smokers (Table 2). Current smokers experienced a twofold increase in risk (adjusted odds ratio [OR] = 2.1, 95% confidence interval (CI) = 1.3, 3.6) compared with never smokers. Women who smoked an average of 10 or more cigarettes per day were at higher risk than those who smoked less (OR = 2.4, 95% CI = 1.4, 4.2 vs OR = 1.2, 95% CI = 0.5, 3.0). The risks associated with current smoking were consistently higher among women with two or more recent sexual partners (Table 3). The percentage of current smokers did not differ between partners of case and partners of control patients (35% and 30%, respectively).

Discussion

Although we were able to represent a broader spectrum of disease by including outpatients and were able to use a population-based series of control patients, our data have certain limitations. Diagnostic misclassification was unavoidable because laparoscopic confirmation was not done in the majority of cases. Also, we could not obtain complete microbiological data, which prevented us from examining how types of infection might modify the association with smoking.

Since many of the variables associated with increased risk of PID are also associated with smoking,[10,11] the possibility remains that smoking is a marker for lifestyle attributes inadequately adjusted for in the analysis. Several factors argue against this possibility. First, although lifestyle may be crudely assessed in the available variables, the proportion of women who were current smokers was higher for cases than for controls in virtually all categories of each variable (Table 1). Second, the risk of PID was elevated only among current smokers, which is consistent with expectations for an acute infectious process; among current smokers, moreover, risk increased with increasing amount smoked and with increasing potential for exposure to a variety of infecting organisms (more than one recent sex partner).

[a]Adjusted for age, race, gravidity.

Finally, we noted that the current smoking patterns of respondents' partners were unrelated to respondents' risk.

There are a number of plausible ways in which smoking may increase the risk of PID. The effect of nicotine on tubal ciliary function and ovum transport has been documented,[12] and the same impaired ciliary wave action that can fail to move the ovum toward implantation in the uterus may result in an inability to effectively repel ascending infectious organisms.

Studies have also provided evidence that smoking impairs the immune response.[13–19] A recent examination of the effect of cigarette smoking specifically on local cervical immunity found that current smokers had a decrease in the concentration of Langerhans' cells in the cervical epithelium.[20] Because these cells help detect and present antigens to circulating T-lymphocytes, a decrease could affect susceptibility to PID pathogens.

The only other study to assess this relationship used hospital-based data from the Women's Health Study[7]; the OR for current smokers compared to never smokers was 1.7. Our findings agree with findings from studies of PID sequelae, as well.[1–6] An association between smoking and urethritis in men, which is caused by many of the same organisms that cause PID,[21] has also been reported.[22]

More information is needed about modifiable noninfectious factors that may be associated with the acquisition or spread of cervical infection. This population-based study describes an association between one such factor—current smoking—and acute PID. We provide evidence that uncontrolled confounding is not the source of these findings and show that there is reason to believe that smoking itself may be acting to increase the risk of acute PID. □

Acknowledgments

This research was supported in part by grants 1-R01-HD17657 and 3-R01-HD17657-S1 from the National Institute of Child Health and Human Development, National Institutes of Health.

These findings were reported in part at the Society for Epidemiological Research 23rd Annual Meeting in Snowbird, Utah, June 1990.

The authors would like to acknowledge Noel Weiss, Kathleen Saunders, Barbara Young, Sandra Howard, Carol Ure, Jude Ballard, and the interviewing team that collected these data for their assistance with this project.

Dr. Derrick B. Jelliffe to Receive Posthumous Award at APHA Annual Meeting

Dr. Derrick B. Jelliffe will posthumously receive the "Lifetime Achievement Award" from APHA's International Health Section at this year's APHA meeting in Washington, DC, November 8 to 12. (Dr. Jelliffe, a renowned pediatrician and advocate for international maternal and child health and nutrition, as well as professor emeritus at the University of California–Los Angeles School of Public Health, died March 18 at the age of 71.) The tribute will take place Tuesday, November 10, from 7:00 to 8:30 PM. Dr. Susi Kessler, chair of the International Health Section, will present the award. Dr. Michael C. Latham, professor and director of the Program in International Nutrition, Cornell University, will deliver the tribute's keynote address, "Derrick Jelliffe: Pioneer in Child Health and Infant Feeding." A reception will follow.

Lead Exposure and Child Behavior

ABSTRACT

Objectives. Unlike cognitive impairments associated with lead exposure, lead-associated child behavior problems have been difficult to specify, particularly in young children.

Methods. The Child Behavior Checklist (CBCL) and the Center for Epidemiologic Studies Depression Scale were used as the outcome and confounding variables, respectively, of major interest. These measures were examined with respect to blood lead levels of 201 African-American children aged 2 through 5 years.

Results. In comparison with the low exposed group, the high exposed group (two consecutive blood lead levels ≥15 μg/dL) had a significantly higher mean CBCL Total Behavior Problem Score (TBPS) and Internalizing and Externalizing scores; when other factors, including maternal depressive symptomatology, were controlled for, regression procedures indicated a .18-point TBPS increase for each unit increase in lead and a 5.1-point higher TBPS in the high exposed group; children in this group were 2.7 times more likely to have a TBPS in the clinical range.

Conclusions. Through its use of a standardized parent-report measure of behavior and its consideration of maternal morale in multiple linear and logistic regression procedures, this study provides further evidence of lead's detrimental effect on child behavior at levels typical of present-day exposure. (*Am J Public Health.* 1992;82:1356–1360)

Introduction

Lead poisoning is the most important pediatric environmental health problem in the United States.[1] Disturbances in neurological and systemic functions have been identified at levels that were once thought not to be cause for concern (i.e., 10 to 25 μg/dL).[2] There is strong evidence that low-level exposure impairs cognitive development,[3] and long-term effects of childhood exposure have been reported.[4]

Lead-associated behavioral difficulties in young children are insidious and difficult to specify. Nonspecific symptoms (e.g., overactivity, irritability, lethargy) may not be recognized until the child enters school. In this study we examine the influence of lead exposure on maternal-reported behavior in children aged 2 through 5 years.

Because maternal morale may color salient aspects of the early caregiving environment, affecting lead exposure (related to compromised caretaking),[5–8] behavioral development,[9] and maternal perceptions of child behavior,[10] maternal depressive symptomatology is considered in this study as a potentially important confounding factor. Low-income women who live alone with their children are at greater risk for depression.[11,12]

Methods

A convenience sample of 150 mother-child dyads from the Baltimore Soil Lead Abatement Demonstration Project's clinic were enrolled in this study during the period from February through April 1989; 54 dyads from the Kennedy Krieger Institute's Lead Poisoning Referral Center were recruited at their clinic visits in April, May, and June 1989. Recruitment from both a population-based study and a clinical facility for referred children ensured a broad range of lead exposure. All subjects met the following enrollment criteria: (1) the child was between 2 and 5 years old; (2) the mother or female guardian accompanied the child to the clinic; and (3) both were African-American. There were three refusals to participate (Kennedy Institute), resulting in a sample of 201 dyads.

Lead concentrations were determined from venous samples collected during the clinics. Children with a blood lead level greater than or equal to 15 μg/dL on two consecutive occasions—at the clinic appointment immediately prior to enrollment in this study and at the first appointment during the study period—were considered the high exposed group. Consistent with preestablished criteria,[13] children with a free erythrocyte protoporphyrin level greater than or equal to 35 μg/dL and a blood lead level less than 25 μg/dL were considered iron-deficient (in the absence of lead poisoning).

Child behavior was measured by interviewing the mother during the child's clinic visit. The Child Behavior Checklist

At the time of the study, William G. Sciarillo was with Children's Medical Services, Local and Family Health Administration, Department of Health and Mental Hygiene, Baltimore, Md. Greg Alexander is with the Maternal and Child Health Program, School of Public Health, University of Minnesota, Minneapolis, Minn. Katherine P. Farrell is with Community Health Services, Anne Arundel County Health Department, Annapolis, Md.

This paper was submitted to the Journal June 18, 1991, and accepted with revisions April 27, 1992.

(CBCL),[14–16] a standardized scale designed to quantify troublesome parent-reported behaviors, was used. The CBCL is widely accepted as a reliable and valid approach to behavioral assessment.[17]

Maternal depressive symptomatology was measured by interview; the Center for Epidemiologic Studies Depression Scale (CES–D),[18] a 20-item index of the number and frequency of depressive symptoms,[19] was used. A CES-D score of 16 or more is clinically significant (significance has been validated by correlation with clinical ratings of depression and by associations with negative life events) and may also indicate nonspecific psychological distress.[20,21]

Results

There were 123 children in the low exposed (LE) group and 78 in the high exposed (HE) group. Mean blood lead levels prior to this study were 11.3 μg/dL (SD = 4.3) for the LE group and 28.6 μg/dL (SD = 9.3) for the HE group; mean levels during the study were 9.2 μg/dL (SD = 2.9) and 27.8 μg/dL (SD = 10.4), respectively.

Mean CBCL Total Behavior Problem Scores (TBPSs), Internalizing and Externalizing T-scores, based upon the percentile ranking of raw scores, are presented in Table 1. The HE group consistently had more maternal-reported troublesome behaviors. Prevalence of TBPSs, Internalizing, and Externalizing T-scores in the clinical range (90th percentile) are presented in Table 2. The proportion of HE children with clinical T-scores was approximately double that of the LE group.

The prevalence of subscale T-scores in the clinical range (98th percentile) was examined, providing a more specific perspective of maternal-reported behavior problems. Overall, 17.9% of LE children and 30.8% of HE children had one or more subscales in the clinical range (odds ratio = 2.0; 95% CI = 1.0, 4.0).

The prevalence of clinical T-scores for each subscale of the 2- to 3-year-old (both sexes) profile (n = 118), the 4- to 5-year-olds boys' profile (n = 46), and the 4- to 5-year-old girls' profile (n = 37) is presented in Figures 1 and 2. This prevalence was generally higher in the HE group across all three profiles. For 2- to 3-year-olds and for 4- to 5-year-old boys, this tendency was particularly evident toward the Externalizing end of the continuum of the profiles (e.g., for the Aggressive subscale).

Other factors that may have accounted for maternal-reported behavior differences between the two groups were examined. Mean age was 46.4 months (SD = 13.7) for LE children and 44.7 months (SD = 12.9) for HE children ($P = .38$). Maternal education averaged 12.2 years (SD = 1.8) for the LE group and 11.0 years (SD = 1.6) for the HE group ($P < .001$). Mean maternal CES-D scores were 11.3 (SD = 9.9) for the LE group and 13.2 (SD = 9.9) for the HE group ($P = .18$); prevalence of clinical CES-D scores was 25.2% and 34.6%, respectively ($P = .15$). HE children were more likely to come from households in which the mother was not a high school graduate ($P < .001$), was unemployed ($P < .01$), was single ($P < .05$), or was head of the household ($P < .01$), and from

Intercept = 22.97.

[a]Iron deficiency in the absence of lead poisoning (i.e., free erythrocyte protoporphyrin ≥35 μg/dL *and* blood lead <25 μg/dL).

households in which there was an increased likelihood of four or more preschool-aged children in the household ($P < .05$).

When all other variables in the model were simultaneously controlled for through multiple linear regression, a significant increase ($P = .01$) in the TBPS with increasing blood lead levels was found (Table 3). The magnitude of this effect was quite small (the TBPS increased by .18 points for each unit increase in lead). However, when a dichotomous measure of blood lead (LE vs HE group) was substituted in the model and all other variables in the model were controlled for, a 5.1-point higher TBPS was found in HE children ($P = .001$). Maternal CES-D score was the most significant influence on the child's TBPS ($P = .0001$); child's age and maternal education also had significant independent influence. Similar results were found for the CBCL Internalizing and Externalizing scores.

Multiple logistic regression indicated that HE children were 2.7 times more likely to have a TBPS in the clinical range (Table 4). Maternal depressive symptomatology was most influential (odds ratio = 4.7).

Discussion

Young children with blood lead levels greater than or equal to 15 μg/dL on two consecutive occasions presented more maternal-reported maladaptive behaviors than did children with lower blood lead levels. Initial comparisons between the LE and HE groups indicated significantly higher mean TBPSs, Internalizing scores, and Externalizing scores in HE children. These children also had a prevalence of such scores in the clinical range (90th percentile) that was nearly two times higher than that of children in the LE group.

The HE group generally had a higher prevalence of CBCL subscale scores in the clinical range (98th percentile), especially at the Externalizing end of the continuum of the profiles for 2- to 3-year-old children of both sexes and for 4- to 5-year-old boys. Four- to five-year-old girls in the HE group had a higher prevalence of clinical subscales over the entire Internalizing-Externalizing continuum. The subscales represent factor analytically derived behavioral descriptions, not diagnostic inferences. The prevalence of clinical range subscales for LE children was quite similar to those found in previous reports for young children without known biological risk factors.[15(pp 64,65),22]

TABLE 4—Multiple Logistic Regression on Child Behavior Checklist Total Behavior Problem Score in Clinical Range (90th Percentile)

	Model Level	Adjusted Odds Ratio	95% Confidence Interval
Maternal education, y	<12	0.7	0.3, 1.6
Maternal occupation	Unemployed	1.2	0.5, 2.6
Maternal marital status	Not married	2.0	0.6, 6.4
Preschool children in household	≥4	0.2	0.0, 1.0
Maternal CES-D score	≥16	4.7	2.2, 10.1
Child's age, y	4 or 5	0.9	0.4, 1.8
Child's sex	Male	1.1	0.5, 2.4
Iron deficiency only	Yes	0.8	0.2, 3.4
Blood lead group	High exposed	2.7	1.2, 5.7

Note. Likelihood ratio $\chi^2 = 32.10$; $df = 9$; $P < .001$.

The effect of lead on externalizing behaviors (e.g., increased motor activity) has been demonstrated in animal models.[23–25] The association between exposure and "hyperactive" child behavior has been reported in several case-control studies[26–28] and in Needleman et al.'s population-based study, in which a consistent dose-response relationship between lead and teacher-reported nonadaptive behaviors was found.[29] Others reported children with increased lead levels as demonstrating more behavior problems, particularly with respect to conduct, inattentiveness, passivity, and hyperactivity.[30] A related finding is that hyperactive children have been found to have higher urinary lead levels after penicillamine challenge.[31]

When the influence of selected factors was controlled for in this study through multiple regression analyses, the magnitude of the lead-behavior effect was such that higher lead exposure was associated with a 5.1-point increase in the TBPS. Although this association may not appear to be clinically relevant for an individual child, an overall 5-point upward shift in the normal distribution of TBPSs would have resulted in almost 82% more children scoring in the clinical range. Also, the HE group was 2.7 times more likely to have a TBPS in the clinical range. This finding takes on particular significance in view of the pandemic nature of lead exposure at levels greater than or equal to 15 μg/dL in young children.[2]

The most influential factor on the TBPS in both the multiple linear and logistic regression procedures was the maternal CES-D score. This influence can be explained in at least five ways: (1) mother and child share a similar genotype, (2) mother and child may be reacting to a common factor (e.g., poverty), (3) increased maternal depressive symptoms detrimentally influence child behavior, (4) child behavior problems detrimentally influence maternal morale, and (5) mothers with lower morale rate their children's behavior more negatively. It is reasonable to maintain that some indistinct dynamic combination of all five is operational here. Although the cross-sectional design precludes a more specific delineation, including the maternal depressive symptomatology variable in the regression models provided some degree of empirical control for these possible influences.

With respect to the later possible influence, Conrad and Hammen investigated the relationship of maternal depression to perceptions of internalizing and externalizing disorders in children. They reported that maternal depressive symptomatology and psychiatric clinical status were not associated with misperceptions of child behavior problems.[32] Using teacher ratings as an independent criterion for rating the accuracy of maternal ratings, Richters and Pellegrini found no evidence that depressed mood, depressed clinical state, or history of clinical depression attenuated mother-teacher agreement about child behavior problems.[33]

In addition to the epidemiological significance of an increased prevalence of maternal-reported troublesome behaviors at lead levels typical of present-day exposure, a major clinical implication of this study is that young children with reported behavioral difficulties should undergo appropriate lead screening. Also, the care context in which lead evaluation and treatment occur provides an opportunity to address parental concerns about child behavior. Appropriate interventions, including changing parental misconceptions about normal child behavior, can be initiated. The parent-child dyad is often a captive audience during the lead evaluation and treatment process, and the parent may be more receptive to interventions at this time.

The results of this study, with its particular attention to maternal-reported maladaptive behaviors in young children, lends support to a belief that undue lead exposure in early childhood may have a pervasive influence on the prevalence of juvenile delinquency in this country. □

Pregnancy among the Hmong: Birthweight, Age, and Parity

Deborah Helsel, BA, RN, Diana B. Petitti, MD, and Peter Kunstadter, PhD

ABSTRACT

Objectives. **The influx of Southeast Asians into the United States allows for the study of this special population and contributes to a broader understanding of reproductive health.**

Methods. **We used information on birth certificates to identify 1937 Hmong children born 1985 through 1988 in California, and we compared birthweight and reproductive factors as related to these children with the same factors as related to 3776 White, non-Hispanic children born in the same period.**

Results. **Mean birthweight among Hmong children (3311 g) was significantly lower ($P < .05$) than among White children (3452 g), but the proportion of births under 1500 g was higher for Whites. Hmong women were of much higher parity and were more likely to deliver at both a young (< 18 years) and an old (> 40 years) maternal age. At every age and every parity, however, Hmong women had cesarean sections at one-half to one-tenth the rate of White women.**

Conclusions. **Despite a high proportion of births at high parity and advanced maternal age, Hmong women gave birth to very low-birthweight babies at essentially the same rates as White women. Their lower cesarean section rates, however, deserve further attention. (*Am J Public Health.* 1992;82:1361–1364)**

Introduction

The influx of large numbers of Southeast Asian refugees into the United States since 1975 has allowed for studies of the health status and practices of the various ethnolinguistic groups represented in the migration, which in turn have contributed to an understanding of the unique concerns of refugee populations and of reproductive health in general. The most recent wave of Southeast Asian immigration began in 1975 and included the Hmong, an agricultural people who live in relatively remote villages in the mountainous regions of southwestern China and northern Southeast Asia.[1]

As immigrants to the United States, the Hmong were more rural, less educated, less occupationally skilled, and less "Westernized" than earlier arrivals.[2] Most Hmong immigrants had little formal education and did not speak or read English, making communication in U.S. society difficult. Unemployment rates for newly arrived Hmong were well over 50%, and most (about 75%) of these immigrants depended on cash assistance. These factors indicate the difficulties the Hmong have had in adapting to life in the United States.[3]

The primary purpose of our study was to compare reproductive factors among Hmong immigrants with those among White, non-Hispanic women. Hmong women are unlikely to use tobacco or alcohol;[4] however, obstetrical care providers have encountered many other health care problems in Southeast Asian immigrant patients[4–7] that have previously been associated with poor pregnancy outcome. Such problems include low socioeconomic status and late prenatal care.[8,9] Although some of these risk factors among the Hmong might be expected to result in a high proportion of low-birthweight infants, this association has not been noted in related works.[5,10]

Methods

Merced and San Joaquin counties in the Central Valley of California were chosen for this study because of the large concentration of Hmong living there. Birth certificates filed 1985 through 1988 for Merced County and 1986 through 1988 for San Joaquin County were examined to identify singleton live births to Hmong and other Asian women. A random sample of singleton births to White, non-Hispanics in the same counties and years and equal in number to the Asian births was also selected. A total of 3776 Asian births and 3776 White, non-Hispanic births were identified.

To determine ethnicity within the Asian group, the names of both parents were inspected. Ethnicity was assigned using protocols designed with the help of members of the Hmong community. Distinctive spellings and syllable patterns, and lists of Southeast Asian clans and family naming systems, such as the one described in Muecke,[11] eventually made this a straightforward effort. Infants born of mixed marriages (of whom there were very few) were eliminated.

TABLE 1—Percentage Distribution of Birthweight in Singleton Births to Hmong and White Women: Merced and San Joaquin Counties, California

Ethnicity	Births, n	Birthweight Category <1000 g, %	1000–1499 g, %	1500–2499 g, %	2500+ g, %
Hmong	1937	0.1	0.2	4.3	95.4
White, non-Hispanic	3776	0.4	0.2	3.3	96.1

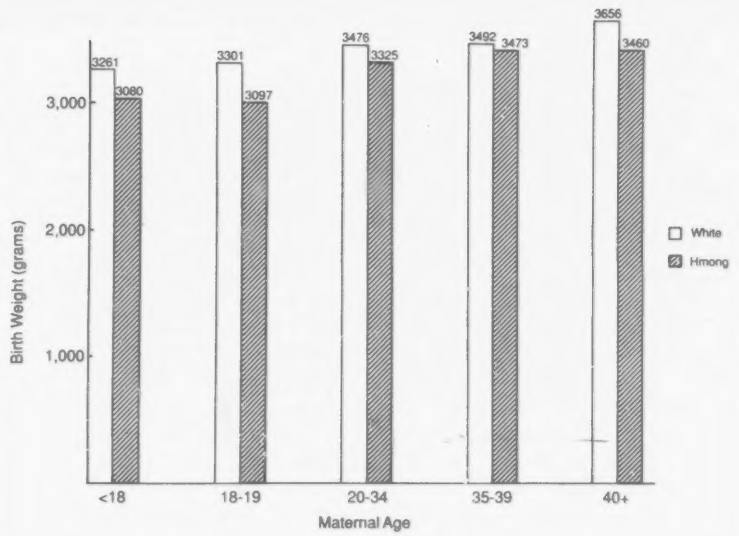

FIGURE 1—Mean birthweight in singleton births to Hmong and White women by maternal age.

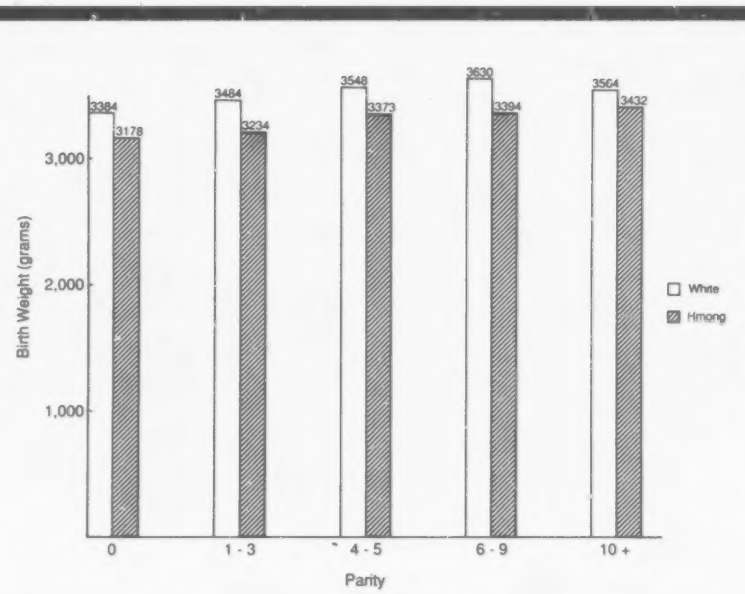

FIGURE 2—Mean birthweight in singleton births to Hmong and White women by parity.

The Asian births included 1937 Hmong. This group was compared with the 3776 White, non-Hispanic births. The statistical significance of differences in birthweight and gestational age were tested using the *t*-statistic for continuous variables. For polychotomous variables, the chi-square statistic was used.

Results

The mean birthweight in singleton Hmong births was 3311 g; in Whites, it was 3452 g ($P < .05$). The overall low-birthweight (< 2500 g) rate for the Hmong was 4.6%, not significantly ($P > .05$) different from that for the Whites (3.9%). Hmong women had a lower proportion of births weighing less than 1500 g than did White women (Table 1), but again, the difference was not significant ($P > .05$). The mean gestational age in the Hmong was 268.3 days; in Whites, it was 272.3 days ($P < .05$).

Parity and maternal age of Hmong mothers differed markedly from that of White mothers. As to parity, 36.6% of Whites and 11.3% of Hmong were primiparous; on the other hand, 41.3% of Hmong and only 2.4% of Whites were para 5 or greater ($P < .05$). As to maternal age, 5.0% of White mothers and 7.9% of Hmong mothers were under age 18 whereas 4.8% of Hmong mothers and 0.8% of White mothers were over age 40 ($P < .05$). Mean birthweight among the Hmong was lower at all parities and ages (Figures 1 and 2).

The overall rate of cesarean sections for Hmong women was 3.9% compared with 23.8% for White women ($P < .05$). The low Hmong rate was not due to age or parity (Table 2).

As a group, White mothers tended to begin prenatal care earlier than Hmong mothers; 71.9% of White mothers had begun care by the third month of pregnancy compared with 34.4% of Hmong mothers ($P < .05$). However, only 0.7% of the Hmong mothers received no prenatal care compared with 2.1% of the White mothers ($P < .05$). These patterns are also reflected in breakdowns defined by parity and maternal age (Table 3). Among Whites but not Hmong, women of very high parity were less likely to enter prenatal care early. Across the maternal age groups, the same generally held true (Table 3), but not all differences were statistically significant.

TABLE 2—Cesarean Section Rate[a] by Maternal Age and Parity in Singleton Births to Hmong and White Women: Merced and San Joaquin Counties, California

Ethnicity	Age					Parity				
	<18	18–19	20–34	35–39	40+	0	1–3	4–5	6–9	10+
Hmong	3.3	5.7	3.6	5.0	4.3	11.0	3.7	1.8	3.3	6.3
White, non-Hispanic	14.8	22.2	23.8	32.6	40.0	24.4	23.8	19.1	17.1	16.7

[a]Prenatal care began in months 1 to 3 of gestation.

Discussion

A previous study[12] found lower birthweight among the Chinese and Japanese in California. Our study shows that lower birthweight among Asians in California extends to the Hmong. Others[5-10] who have reported on birthweight among recent Southeast Asian immigrants to the United States have also found a lower mean birthweight among Southeast Asians compared with Whites. Information on maternal height and weight, which is not available on birth certificates, may explain the lower mean birthweight among the Hmong.

Despite the difference in mean birthweight, there is no statistically significant difference between proportions of Hmong and White births at low (< 2500 g) or very low (< 1500 g) birthweight. The similarity in the percentage of births at low or very low birthweight is most remarkable considering the high proportion of Hmong women delivering at high parity and advanced maternal age, both factors considered to be predictors of poor birthweight outcome. Moreover, although the Hmong live on public assistance, speak little English, and enter prenatal care late, they have a low absolute rate of low birthweight.

The high fertility of the Hmong in California is noteworthy. If high fertility is sustained, a study of the Hmong in California might provide information on the independent association of short interpregnancy interval and high parity with low birthweight, a controversial subject.[13-15]

Cesarean-section rates among the Hmong are strikingly lower than those among Whites in the same counties, even among women having their first child. There are anecdotal reports that Hmong refuse cesarean delivery when it is recommended, but a formal study of this has not been done. Overall complication rates are higher among White mothers than among Hmong mothers (data not shown), but the complications that are higher in Whites include dystocia, failure to progress, prior cesarean, and cephalopelvic disproportion, all of which are as much labels as diagnoses. The low cesarean-section rate among Hmong mothers provides an opportunity to determine the morbidity and mortality of low rates of cesarean section in a modern medical care setting. □

Call for Abstracts for National Student Research Forum

The University of Texas Medical Branch (UTMB) announces the 34th National Student Research Forum, to be held April 15 to 17, 1993, at the UTMB campus in Galveston, Texas. The Forum is intended for the competitive presentation of clinical and basic science research by medical students, graduate students, interns, and residents. It is the sole national meeting of its kind, attended by participants from throughout the United States and Canada. It is supported by grants from the American Medical Association Education and Research Foundation, Roche Laboratories, and the American Academy of Family Physicians.

Abstracts must be postmarked by no later than November 15, 1992. Further information concerning rules and awards may be obtained from the National Student Research Forum, Rm G-210, Ashbel Smith Bdg, Rte M-17, The University of Texas Medical Branch, Galveston, TX 77550; tel. (409) 772-3762.

Neonatal Tetanus in Rural Bangladesh: Risk Factors and Toxoid Efficacy

W. Gary Hlady, MD, MS, John V. Bennett, MD, Aziz R. Samadi, MD, MPH, Jahanara Begum, MBBS, MPH, Abdul Hafez, MBBS, Aminul I. Tarafdar, MBBS, MPH, and John R. Boring, PhD

ABSTRACT

Objectives. Tetanus continues to be a leading cause of neonatal death in Bangladesh as in other developing countries, yet little is known about risk factors or the efficacy of tetanus toxoid in this setting.

Methods. In May 1990, mothers of 6148 infants born alive between March 15, 1989, and March 14, 1990, in 30 rural unions of Rajshahi Division in Bangladesh were interviewed. Three surviving controls for each neonatal tetanus death were matched for sex, residence, and date of birth.

Results. Of 330 neonatal deaths, 112 met the case definition for tetanus. Risk was increased with a history of neonatal tetanus in a previous child, application of coconut oil to the vagina, and use of multiple ties on the umbilical cord. Risk was reduced by the birth attendant washing hands and using a cleaned cord-cutting tool. Risk was not reduced by a maternal history of two doses of tetanus toxoid (TT2), although estimated efficacy of TT2 was 45% (95% confidence interval = 16% to 64%). Subsequent to the survey, a reference laboratory reported no potency in three consecutive lots of tetanus vaccine from the production laboratory in Bangladesh.

Conclusions. These findings identify high-risk mothers, stress the importance of washing hands and cleaning the cord-cutting tool, and demand improved quality control of tetanus vaccine production. (*Am J Public Health.* 1992;82:1365–1369)

Introduction

Neonatal tetanus continues to be a major cause of death in developing countries, accounting for more than 654 000 deaths in 1990,[1] yet few analytic studies have been done. The value of such studies was most recently demonstrated by a report from Pakistan, which suggested that the risk of neonatal tetanus could be significantly reduced by eliminating the application of ghee (clarified butter) to the umbilical stump during the first several days of life—a common practice in that country and a previously unidentified risk factor.[2] Neonatal tetanus can be totally prevented both by two injections of tetanus toxoid vaccine (TT2) to the mother, with the second dose at least 4 weeks after the first and at least 30 days prior to delivery, and by sterile cord care. But vaccination coverage of pregnant women in most developing countries remains low, and unsafe birth practices persist.[1]

Bangladesh has one of the highest rates of neonatal tetanus in the world.[1] The government has addressed this problem through a vigorous program of vaccination, training of traditional birth attendants, and promotion of safe-delivery kits. In addition, a national study was begun in February 1990 to identify risk factors for neonatal tetanus. This study, which was patterned after the study in Pakistan, was conducted by Global 2000, Inc, in collaboration with the Ministry of Health and Family Planning, and the Task Force for Child Survival and Development. We report here the results of the Rajshahi Division survey, with emphasis on the findings not only of potential risk factors but also of the low efficacy of tetanus toxoid, apparently due to the use of low-potency vaccine.

Methods

Study Population

Bangladesh is divided into four administrative divisions of approximately equal populations. The survey reported here was of Rajshahi Division, occupying the northwest quadrant of the country with a 1981 rural population of 20 009 351.[3] Cluster sampling was done according to World Health Organization (WHO) guidelines.[4] Thirty rural unions (average population 18 000) were systematically selected from the total of 1089 listed in the 1981 census by using a random start and a sampling interval equal to the cumulative population divided by 30, making the probability of selection proportionate to population size. Urban areas were excluded.

Each union is divided into three wards of approximately equal populations, and each ward is divided into a variable number of *mauzas* (average population 1400). The starting point for the survey in each selected union was the first

[b]Two doses of tetanus toxoid at least 4 weeks apart, with the second dose at least 30 days before delivery.

household encountered in a *mauza* selected by use of a random number table. The survey then proceeded from house to house within the same ward until a target of 67 mothers of eligible infants were interviewed. An eligible infant was one who was born alive between March 15, 1989, and March 14, 1990. The survey continued then from the nearest house in the next nearest ward and so on until all three wards were surveyed, for a total target of 201 interviews in each selected union. Interviews completed in excess of the target (usually 3 or 4 per union) were also included in the analysis.

Interviews were conducted by 10 teams of six female interviewers using a standardized questionnaire. Interviewers received 6 days of instruction by Global 2000 staff and faculty of the National Institute of Preventive and Social Medicine, and 4 days of closely supervised field testing. The survey was completed between May 3 and May 28, 1990.

Case Definition

This was a case-control study. A case was an eligible infant who was normal at birth but who died at 3 to 30 days of age following illness, with generalized spasms and at least three of the following four signs: trouble opening mouth, cessation of sucking, clenched hands, and boardlike rigidity. Infants who were seen at a health care facility and given a diagnosis other than tetanus (as reported by the mother) were excluded as cases.

Control Selection

Three living infants—matched for sex, residence (union), and date of birth to control for the effects of circumcision, regional variations in birth practices, and recall—were selected as controls for each case. When more than three infants were eligible as controls, priority for selection was given to those with birth dates closest to the case's and to those who resided in the same ward, in that order. Control selection differed from that used in the Pakistan study in that the mothers' vaccination status with tetanus toxoid was disregarded in selecting control infants.

Data Analysis

Data were double entered into an Epi Info, Version 5, data file and were analyzed using the same software package.[5] Univariate analysis of matched data used the same calculations as stratified Mantel-Haenszel analysis to calculate matched odds ratios, with each stratum consisting of a single matched case-control group. The 95% confidence intervals (CIs) for matched odds ratios were calculated using standard methods,[6] and all probabilities were based on two-tailed tests.

Multivariate analysis was performed using EGRET software.[7] Data were defined by the DEF program for conditional logistic regression and analyzed by the PECAN program.[7] The log likelihood ratio statistics, degrees of freedom, and probability statistics for the model, and the 95% CIs and *P* values for each variable, were calculated by the program. Interaction was examined by evaluating the *P* value for main and product terms as well as significant differences in likelihood ratio statistics between noninteractive and interactive models. Multicolinearity among covariables was examined by modeling and correlation procedure.

Vaccine efficacy based on the entire study population was calculated using the following formula: $(Iu-Iv)/Iu$, where Iu is the incidence of neonatal tetanus in infants with no maternal history of tetanus toxoid vaccine prior to delivery and Iv is the incidence of neonatal tetanus in infants with a maternal history of TT2. This formula is equal to $1-(Iv/Iu)$, or 1–(risk ratio), and 95% CIs for the risk ratio were used to calculate confidence intervals for efficacy.[8] Because vaccine efficacy was not an anticipated issue, incidence rates could not be weighted to account for differences in sample union populations. However, the difference between weighted and unweighted rates using this sampling procedure (the EPI method) is considered small and acceptable.[9]

Results

Descriptive Statistics

A total of 43 791 households were surveyed, and the mothers of 6148 eligible infants were interviewed. The circumstances of delivery are summarized in Table 1. There were 330 neonatal deaths (occurring up to 30 days of age). One hundred twelve neonatal deaths met the case definition for tetanus, resulting in a neonatal tetanus death rate of 18.2 per 1000 live births in our study population. Three infants who otherwise met the case definition were excluded because they had been seen at a health care facility and the mothers reported a cause of death other than tetanus (two "evil spirits," one "milk disease"). Only 21 (18.8%) of the cases were seen at a health care facility.

Male cases tended to be seen more often than female cases at a health care facility (23% vs 15%, $P = .3$), but the proportion of males among cases (50.9%) did not differ from that among all live births (51.1%).

None of the male infants was circumcised before 30 days of age.

The dates of birth for cases and for all live births are shown in Figure 1. The cyclic pattern of live births is identical with that observed prospectively in Matlab, Bangladesh.[10] The July through November peak in neonatal tetanus deaths has also been previously observed in India.[11–13] The mean age at death for cases was 10.7 days (SD = 6.3); the median age was 8 days.

Application of substances to the vagina and to the cord stump at the time of delivery were common practices and usually involved the use of mustard oil, which was heated before use. Mustard oil was also commonly applied several times to the cord stump during the first few days of life. Ghee was never applied to either the vagina or the cord stump.[2] Cow dung was applied to the cord stumps of only three infants on the day of delivery, one of whom died of tetanus. Cow dung was also applied to the cord stumps of eight infants only on days subsequent to birth, and none of those infants died of tetanus.

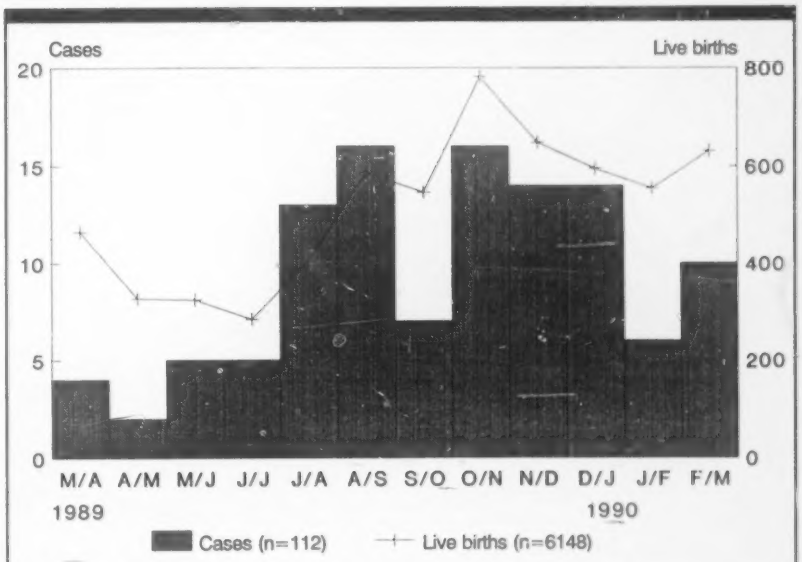

FIGURE 1—Month (English equivalent of Bengali month) of birth for neonatal tetanus cases and all live births.

TABLE 2—Multivariate Analysis[a] of Risk Factors for Neonatal Tetanus

	Coefficient	Standard Error	Odds Ratio	95% CI	*P*

Note. Likelihood ratio statistic on 5 *df* = 34.711, *P* < .001.
[a]Conditional logistic regression by PECAN procedure.[7]
[b]Two doses of tetanus toxoid at least 4 weeks apart, with the second dose at least 30 days before delivery.

Risk Factors

The results of a multivariate analysis of risk factors for neonatal tetanus are shown in Table 2. The striking finding was that a maternal history of TT2 failed to be protective. However, hand washing and the use of a cleaned tool to cut the umbilical cord, regardless of what tool was used, were both associated with decreased risk. The risk increased when coconut oil was applied to the vagina and when the umbilical cord was tied in more than one place.

A history of neonatal tetanus in a previous child was a significant risk factor; its odds ratio, obtained by conditional logistic regression as a single variable in the model, was 3.63 (95% CI = 1.30, 10.14; $P = .01$), but it was excluded from the final model because of colinearity with hand washing. This statistical association was also confirmed by stratified Mantel-Haenszel analysis. Such a history was present in 27.7% (31/112) of cases and in only 7.7% (26/336) of controls. Of previous children born to case mothers, 14.3% (39/273) were reported to have died of neonatal tetanus, compared with 4.5% (33/740) of previous children born to control mothers ($\chi^2 = 29.14$, $P < 10^{-6}$). The mean total number of live births was 3.4 (SD = 2.6) for mothers of cases and 3.2 (SD = 2.2) for mothers of controls. Similarly, mean maternal age was 26.1 years (SD = 6.3) for cases and 25.5 years (SD = 5.7) for controls.

Other factors of interest, including use of a safe-delivery kit, washing of the perineum, application of substances to the umbilical cord, and the presence of a trained birth attendant (8 cases, 35 controls), were not associated with risk and thus were not included in the final regression model.

Efficacy of TT2

The maternal vaccination status at the time of delivery for neonatal tetanus cases and all other live births in our study population is shown in Table 3. The efficacy of a maternal history of TT2, based on these figures, was 45% (95% CI = 16%, 64%). The efficacy of a maternal history of TT2, based on the odds ratio obtained by multivariate analysis of the case-control data, was 24% (95% CI = −29%, 55%). Although less precise, the latter efficacy estimate may be more valid as it is adjusted for the effects of other risk factors. However, both estimates are far below the level expected for a potent vaccine. Verification of vaccination by medical records was difficult to achieve because the medical records were kept with mothers, and only 48.3% of all mothers with a history of TT2 (1209/2505) possessed a medical record at the time of interview.

Discussion

The accuracy of our case ascertainment is supported by the fact that the rate of neonatal tetanus death observed in our study population is similar to that reported by others.[14–16] Had we used a less restrictive case definition of only a history of generalized spasms preceding death during the first 30 days of life, as has been used elsewhere,[17] the number of neonatal tetanus deaths in our sample would have increased to 259 (42.1 per 1000 live births). A similar increase would have resulted

TABLE 3—Maternal Vaccination Status at Time of Delivery

	Neonatal Tetanus Cases (n = 112)		No Neonatal Tetanus (n = 6036)		All live births (n = 6148)	
Vaccination Status	No.	%	No.	%	No.	%
None[a]	56	50.0	2278	37.7	2334	38.0
History of TT1[b]	23	20.5	1286	21.3	1309	21.3
History of TT2[c]	33	29.5	2472	41.0	2505	40.7

[a]Never vaccinated.
[b]Received one dose of tetanus toxoid at least 30 days before delivery. (May have received a second dose less than 30 days before delivery.)
[c]Received two doses of tetanus toxoid, with second dose at least 30 days before delivery.

had we relied only on the mothers' report of cause of death. We chose the more specific case definition to maximize the accuracy of diagnosis for the purpose of identifying risk factors, but this may have also resulted in an underestimate of the incidence of neonatal tetanus death.

Our observation that tetanus toxoid failed to provide the expected high level of protection was not the first to indicate that there may be a problem with the Bangladesh vaccine. Anecdotal reports from physicians had already described apparent vaccine failures; and a 1989 WHO survey of more than 4000 live births, equally divided between areas with high vaccine coverage and areas with low vaccine coverage, found almost twice the expected rate of neonatal tetanus death in the high coverage area.[18]

Subsequent to our findings, a WHO reference laboratory reported no potency in samples from three consecutive lots of tetanus toxoid produced in Bangladesh in July 1990 (J. Milstien, WHO, personal communication, October 17, 1990), and a serosurvey of 100 women vaccinated in September and October 1990 with two doses of tetanus toxoid vaccine found that only 31% had developed protective levels of antibody (N. Abiprojo, UNICEF, personal communication, July 29, 1991).

Since 1983, routine potency testing of tetanus toxoid in Bangladesh has been performed in the same facility by the same staff that produced all the tetanus toxoid vaccine for the national immunization program. There is no national control authority in Bangladesh to certify vaccine safety or potency. Currently, tetanus toxoid production in Bangladesh has been suspended, and the immunization program has continued with the use of imported vaccine.

It has not yet been determined when the problem with vaccine quality control began. Documented vaccination histories from Rajshahi suggest that the problem existed with vaccine in the field at least as early as February 1989. With a 1- to 3-month-long distribution "pipeline," this would include all vaccine produced since January 1989—approximately two thirds of all tetanus vaccine ever produced in Bangladesh—with more than 40 000 000 doses administered. It is possible that the problem was intermittent, but this cannot be determined from available information as no records are kept of the distribution of vaccine by lot number.

Nevertheless, a potent preparation of tetanus toxoid is one of the safest, most effective vaccines available and is the primary element of any neonatal tetanus control program.[1,14] Bangladesh has achieved a remarkably high level of vaccine distribution. If immunization activities are sustained, corresponding decreases in tetanus mortality can be expected with the introduction of a potent vaccine. The very high risk associated with a maternal history of previous neonatal tetanus death, which was initially observed elsewhere[2] and was confirmed in this study, should make this group of women a particularly high priority for immunization.

Failure of the tetanus vaccine in Bangladesh, however, must also serve as a reminder that such high-technology interventions are not always effectively implemented and should not be relied upon solely, especially where simple measures such as hand washing and cleaning of the cord-cutting tool have proven effective and reliable.

The use of a trained traditional birth attendant was not observed to be protective, possibly because of inaccuracies in both the mothers' ascertainment of attendant training and the low number of trained attendants involved. For these reasons and because certain behaviors of the birth attendants were significantly related to decreased risk, our results should not discourage the training of traditional birth attendants as a control measure for neonatal tetanus. Similarly, the low number of safe-delivery kits used did not allow a meaningful evaluation of their effect.

The increased risk associated with the use of multiple cord ties has not been observed elsewhere and awaits further clarification. However, the increased risk associated with the vaginal use of coconut oil is an important finding and is in line with the risk associated with the vaginal use of ghee in Pakistan (H. Traverso, personal communication, December 18, 1990). The mechanism by which the vaginal use of coconut oil increases the risk of neonatal tetanus is unknown, but the increased risk could be due to contamination of the oil by the uncleaned hands of the birth attendant.

Unfortunately, control of neonatal tetanus in Bangladesh will be delayed due to the failure to maintain vaccine potency. Given that fewer than one in five neonatal tetanus cases had contact with the health care system and that the problem with the tetanus vaccine was not brought to light earlier, the need for improved surveillance to evaluate program effectiveness and to monitor vaccine quality and distribution in the field is indicated. Such improvement should include the creation of a separate quality control laboratory and a national control authority. More work is needed to determine how surveillance might best be structured and what thresholds for action are appropriate. □

Improving Estimates of HIV-1 Seroprevalence among Childbearing Women: Use of Smaller Blood Spots

Neil J. Hoxie, MS, James M. Vergeront, MD, John R. Pfister, BS, Gary L. Hoffman, BS, Pamela A. Markwardt-Elmer, BS, and Jeffrey P. Davis, MD

ABSTRACT

Objectives. **Nationwide, human immunodeficiency virus type 1 (HIV-1) seroprevalence surveys using dried neonatal blood specimens are critical to estimating HIV-1 seroprevalence among childbearing women. However, the noninclusion of blood specimens deemed "quantity not sufficient" (QNS) for HIV-1 antibody testing potentially introduces bias. In Wisconsin beginning in 1990, we modified the survey protocol to reduce QNS rates and assess bias introduced by QNS specimens.**

Methods. **The HIV-1 antibody assay was modified to use four 1/8-in blood spots when a single 1/4-in blood spot could not be obtained. Both methods obtain identical blood volumes for testing.**

Results. **During a 27-month period, 7396 (4.8%) of 154 683 specimens were deemed QNS using 1/4-in blood spots. Of these, 6590 (89%) were of sufficient quantity to be tested using four 1/8-in blood spots; 6 (0.09%) specimens tested with 1/8-in blood spots were HIV-1 Western blot assay positive compared with 44 (0.03%) of 147 287 1/4-in specimens (odds ratio = 3.0; 95% confidence interval = 1.2, 7.4).**

Conclusions. **Because noninclusion of QNS specimens potentially introduces bias, incorporating the results of HIV-1 antibody testing of QNS specimens using four 1/8-in blood spots can improve the accuracy of HIV-1 seroprevalence estimates in these serologic surveys. (*Am J Public Health.* 1992;82:1370–1373)**

Introduction

In the United States, surveillance of acquired immunodeficiency syndrome (AIDS) has demonstrated increasing morbidity among both women and children of women with human immunodeficiency virus type 1 (HIV-1) infection.[1,2] Responding to the epidemic of HIV-1 infection among women and children requires accurate information on the prevalence and distribution of this infection within these populations. To provide this information, the Centers for Disease Control (CDC) and the National Institute for Child Health and Development have developed a standard survey protocol for estimating HIV-1 seroprevalence among childbearing women. This protocol uses dried neonatal blood specimens collected on filter paper as part of newborn screening programs for blinded HIV-1 antibody testing. By March 1990, surveys using this protocol were ongoing in 43 states.[3] One such survey has been conducted since 1989 by the AIDS/HIV Program of the Wisconsin Division of Health and the Wisconsin State Laboratory of Hygiene in collaboration with the CDC.

The standard protocol for this survey specifies that 100% of blood specimens received by newborn screening programs during specified periods be tested for HIV-1 antibody.[4] However, attaining this goal is difficult. After mandated newborn screening tests are completed, some specimens are inevitably designated as being of a "quantity not sufficient" (QNS) for HIV-1 antibody testing. The inability to test QNS specimens can result in sampling bias if the prevalence of HIV-1 antibody among QNS specimens is different from that among specimens available for testing. If sampling bias is operative, the accuracy of HIV-1 seroprevalence estimates may be adversely affected.

To investigate whether an adverse effect has occurred in Wisconsin, beginning in 1990 dried blood specimens designated as QNS using standard specimen preparation methods were tested for HIV-1 antibodies using an alternate method. Objectives of the study included determining whether use of the alternate specimen preparation method could decrease the number of QNS specimens and whether the noninclusion of QNS specimens does bias estimates of HIV-1 seroprevalence among childbearing women.

Methods

The standard CDC protocol for blinded HIV-1 seroprevalence surveys using dried neonatal blood specimens has been previously described.[3] Briefly, as relates to this study, capillary blood specimens from neonates born in Wisconsin are collected on a standardized filter paper form, air dried, and sent to the Newborn Screening Unit of the Wisconsin State Laboratory of Hygiene. Duplicate and unsatisfactory specimens are excluded from the survey; only one specimen obtained

Neil J. Hoxie, James M. Vergeront, and Jeffrey P. Davis are with the Bureau of Public Health, Wisconsin Division of Health, in Madison, Wisconsin. John R. Pfister and Pamela A. Markwardt-Elmer are with the Retrovirus Immunology Unit, and Gary L. Hoffman is with the Newborn Screening Unit, of the Wisconsin State Laboratory of Hygiene in Madison.

This paper was submitted to the Journal September 23, 1991, and accepted with revisions May 5, 1992.

from children of multiple births is included. The remaining specimens are eligible for inclusion in this survey once routine, mandated newborn screening tests are completed and personal identifiers have been removed.

Specimens are prepared for HIV-1 antibody testing by punching a blood spot from an area of filter paper judged to be adequately saturated with blood. In Wisconsin, blood spots are routinely obtained using an automated 1/4-in-diameter circular punch (Fundamental Products, North Hollywood, Calif). Use of 1/4-in blood spots is specified in the CDC protocol and is referred to herein as the standard method. If the surface area of blood-saturated filter paper is insufficient to allow a standard punch, the specimen is considered QNS. In this study, if a specimen was deemed QNS, a manual 1/8-in punch (McGill Metal Products, Marengo, Ill) was used to obtain four 1/8-in-diameter circular spots from specimens with sufficient blood-saturated surface area. This is referred to herein as the alternate method. Both the standard and the alternate punching methods result in the collection of an identical surface area of blood-saturated filter paper and thus an identical volume of blood for HIV-1 antibody testing.

Standard and alternate specimens were tested by the Wisconsin State Laboratory of Hygiene's Retrovirus Immunology Unit for HIV-1 antibody using identical procedures, which have been previously described.[5,6] Specimens were tested by enzyme-linked immunosorbant assay (ELISA) (Abbott Laboratories, Chicago, Ill) and were retested in duplicate if reactive. If one or more of the repeat assays were reactive, a Western blot assay (Organon Tecknika, Durham, NC) was performed on the same specimen. Specimens were considered HIV-1 antibody positive if at least two bands from among p24, gp41, and gp120/160 were present on the Western blot.[7]

Parallel testing, using 20 samples each of HIV-1 antibody negative and high and low HIV-1 antibody positive dried blood controls provided by the CDC, was conducted to determine if HIV-1 ELISA results for standard and alternate blood spots were comparable. Comparability was also assessed using a panel of 31 HIV-1 antibody positive and 30 HIV-1 antibody negative dried blood specimens prepared by the Retrovirus Immunology Unit. In addition, a CDC proficiency panel consisting of 12 specimens of unknown HIV-1 reactivity was analyzed by both HIV-1 ELISA and Western blot assay using 1/8-in blood spots, and the observed results compared with those expected by CDC referees. Only after the test methods were judged comparable were the small spot specimens included in the survey.

TABLE 1—Results of HIV-1 Antibody Testing of Dried Blood Spots of Filter Paper Impregnated with Neonatal Blood, Wisconsin, January 1990 through March 1992

	Standard (1/4-in) Punches[a]			Alternate (1/8-in) Punches[b]					
	Tested	HIV+	%+	Tested	HIV+	%+	Odds Ratio	95% CI	*P*
Maternal race									
White	126 024	17	0.01	5311	2	0.04	2.6[c]	1.0, 6.3[c]	.06[c]

Total	147 287	44	0.03	6590	6	0.09	3.0	1.2, 7.4	.02

[a]Specimens were obtained with 1/4-in punch as specified in the standard Centers for Disease Control protocol.
[b]Specimens were deemed "quantity not sufficient" (QNS) by standard methods and were obtained using four 1/8-in punches.
[c]Statistical analysis compared alternate punched specimens with standard punched specimens, adjusted using the Mantel-Haenszel method.
[d]Minority category includes all races other than White; Hispanic may be classified as either White or minority.

Data were analyzed using Epi Info, Version 5.0, software (CDC, Atlanta, Ga). Statistical tests included odds ratios (ORs), Cornfield's 95% confidence intervals (CIs) of odds ratios, and tests of significance using either the Yates Corrected χ^2 test if all individual cells were greater than or equal to 5, or Fisher's Exact Test if any individual cell was less than 5. Adjusted analysis was performed using the Mantel-Haenszel method.[8] Results of parallel testing of CDC blood spot controls were compared using a *t* test; absorbance ratios of comparison panel specimens were compared using a paired *t* test.

The HIV-1 seroprevalence rate is the proportion of specimens tested that was HIV-1 Western blot positive. The QNS rate is the proportion of the total sample determined to be QNS by standard punching methods. The salvage rate is the proportion of QNS specimens that could be sampled using multiple 1/8-in punches. Bias factor is defined as the HIV-1 seroprevalence rate among specimens tested using 1/8-in spots divided by the rate among 1/4-in specimens. If "Sero A" refers to the combined total seroprevalence of 1/4-in and 1/8-in blood spots and "Sero B" to the seroprevalence of only 1/4-in spots, relative error (RE) can be defined as ([Sero A − Sero B]/ Sero A) × 100. RE can also be expressed as a function of the QNS rate and the bias factor: RE = QNS rate × (bias factor − 1) × 100.

Results

From January 1990 through March 1992, a total of 154 683 specimens were eligible for inclusion in this survey. Of these, 7396 (4.8%) were deemed of insufficient quantity to test for HIV-1 antibody using a standard 1/4-in punch. The QNS rate was higher among specimens collected from minority neonates (1457/22 715, 6.4%) than among specimens from White neonates (5937/131 961, 4.5%) ($P < .001$, Yates Corrected χ^2), and higher among specimens collected from neonates with teenage mothers (885/16 204, 5.5%) than among specimens from neonates with older mothers (6508/138 457, 4.7%) ($P < .001$, Yates Corrected χ^2) (Table 1).

Sufficient acceptable specimen was available to obtain four 1/8-in blood spots from 6590 (89%) of the 7396 QNS specimens. The salvage rate was similar among specimens from White neonates (5311/5937, 89%) and minority neonates (1279/1457, 88%), as it was among specimens from neonates with teenage mothers (793/885, 90%) and neonates with older mothers (5796/6508, 89%).

The HIV-1 seroprevalence rate among specimens punched using the alternate method was threefold greater (.09% vs .03%) than that among specimens punched using the standard method

(odds ratio [OR] = 3.0; 95% confidence interval [CI] = 1.2, 7.4; $P = .02$, Fisher's Exact Test) (Table 1). After adjusting for race, the point estimate of the adjusted OR (2.6) was slightly less than that of the crude OR (3.0). Adjusting for maternal age resulted in an OR identical to the crude OR. Using only 1/4-in blood spots, the estimate of HIV-1 seroprevalence among childbearing women is 0.0299%; when 1/4-in and 1/8-in blood spot test results are combined, however, the HIV-1 seroprevalence estimate increases 8.7% to 0.0325%.

The results of 20 HIV-1 ELISA procedures performed on the negative CDC control specimen demonstrated a mean absorbance ratio of 0.32 (range = .22 to .43) for 1/8-in blood spots compared with 0.37 (range = .27 to .50) for 1/4-in blood spots ($P < .01$). Twenty HIV-1 ELISA procedures performed on the low positive CDC control specimen produced a mean absorbance ratio of 2.68 (range = 2.36 to 3.21) for 1/8-in blood spots and 2.46 (range = 1.62 to 3.30) for 1/4-in blood spots ($P = .07$). Twenty HIV-1 ELISA procedures performed on the high positive CDC quality control specimen resulted in a mean absorbance ratio of 8.29 (range = 7.25 to 10.04) for 1/8-in blood spots and 7.26 (range = 5.36 to 8.59) for 1/4-in blood spots ($P < .01$).

For both 1/8-in and 1/4-in negative control blood spots, HIV-1 ELISA absorbance ratios were all well below the testing laboratory's cutoff absorbance ratio (< 1.0) for nonreactive HIV-1 ELISA; thus, no misclassification of HIV-1 serostatus occurred among negative specimens. The absorbance ratios of all low and high positive CDC quality control specimens tested using 1/8-in and 1/4-in blood spots were all well above the cutoff absorbance (≥ 1.0) for reactive HIV-1 ELISA; thus, no misclassification of HIV-1 serostatus occurred among positive specimens.

Comparison of paired HIV-1 ELISA test results (1/8-in blood spots vs 1/4-in blood spots) of the HIV-1 negative and the HIV-1 positive comparison panels prepared by the testing laboratory demonstrated no discordant classification of HIV-1 serostatus. Paired analysis of the 30 HIV-1 negative panel specimens showed the mean of the absorbance ratio differences to be -.022 (SE = .023; $P = .33$, paired t test). Paired analysis of the 31 HIV-1 positive panel showed the mean of the absorbance ratio differences to be -.082 (SE = .10; $P = .41$, paired t test).

HIV-1 ELISA testing of the 12 CDC proficiency panel specimens using 1/8-in blood spots resulted in the correct HIV-1 classification for each specimen. In this panel, the expected banding patterns of the Western blot assays were demonstrated on each of the six specimens derived from the 1/8-in blood spots that yielded reactive HIV-1 ELISA results.

Discussion

Our findings demonstrate that, in HIV-1 seroprevalence surveys that use dried neonatal blood specimens, QNS rates can be reduced by using multiple 1/8-in blood spots to analyze specimens that are of insufficient quantity to test using a standard 1/4-in punch. Use of this technique provided an opportunity to analyze 89% of specimens that would otherwise have been unavailable for HIV-1 antibody testing.

Our comparison studies indicate that, although multiple 1/8-in blood spots may produce different absorbance ratios on HIV-1 ELISA, HIV-1 antibody testing of these small spots results in an HIV-1 antibody status classification identical to that obtained testing standard-size blood spots. This suggests that multiple 1/8-in blood spots can be reliably tested for HIV-1 antibody with the Abbott assay using the same testing methods as for 1/4-in spots. Laboratories that use other assays should conduct parallel testing to confirm the comparability of results.

The presence of QNS specimens would have no adverse effect on overall estimates of HIV-1 seroprevalence if the seroprevalence of QNS specimens were similar to that of specimens tested using standard punches. However, an important finding of this study is that the prevalence of HIV-1 antibody among QNS specimens was threefold greater than that among specimens available by standard sampling methods; this observed difference was independent of maternal race and age. In our study, use of multiple 1/8-in blood spots increased the number of HIV-1 seropositive specimens by 14% and the estimate of HIV-1 seroprevalence among childbearing women by nearly 9%. Thus, the occurrence QNS specimens *can* bias HIV-1 seroprevalence estimates.

Reasons for the occurrence of QNS specimens probably differ from state to state. They could result from inadequate specimen collection although, in Wisconsin, poorly collected specimens are not accepted for newborn screening and a second specimen is requested. It has been the experience of the Wisconsin Newborn Screening Unit, however, that many QNS specimens have had additional newborn screening tests performed by necessity on the initial sample (Gary L. Hoffman, unpublished data). This additional testing results when the values for initial newborn screening tests fall outside of established limits, in which case it is laboratory policy to repeat those tests. Additional testing results in an increased consumption of the blood specimen, which may result in an insufficient quantity of dried blood to allow HIV-1 antibody testing.

The reasons for our finding of higher HIV-1 seroprevalence among QNS specimens are unclear. It is possible, however, that the requirement for additional testing, which leads to QNS specimens, may be associated with—among other factors—low birthweight. It has been observed that low-birthweight infants are more likely to have newborn screening test results, particularly those for thyrotropin and thyroxine, outside the acceptable limits established by the newborn screening laboratory. Additionally, low-birthweight infants are more likely to be treated with antibiotics, aminosin, or total parenteral nutrition compared with normal birthweight infants. Because these treatments can interfere with some newborn screening assays, spurious laboratory values can result, increasing the need for additional testing.

A correlation of QNS specimens with low birthweight could help explain the association of QNS specimens with teenage mothers and minority status. In Wisconsin, low birthweight is associated with both of these characteristics[9]; in New York City, it was found to be closely correlated with newborn HIV seropositivity.[10] And while the etiology of low birthweight is multifactorial, in some cases it is associated with injection drug use,[11–13] which in turn is strongly associated with HIV-1 infection among women and their children.[14,15] Thus, although this conclusion is speculative, the higher HIV-1 seroprevalence among specimens obtained using 1/8-in punches could be a result of an increased prevalence of maternal intravenous drug use among neonates with QNS neonatal blood specimens.

In certain situations, larger relative errors resulting from QNS bias are plausible. As shown in Figure 1, relative error introduced by this effect is a function of both the QNS rate and the bias factor. The relative error produced could be of public health significance, even at moderate QNS rates. For example, with a QNS rate of 10%, HIV-1 seroprevalence could be underestimated by 10% if the bias factor is equal to 2 and by 40% if the bias factor is

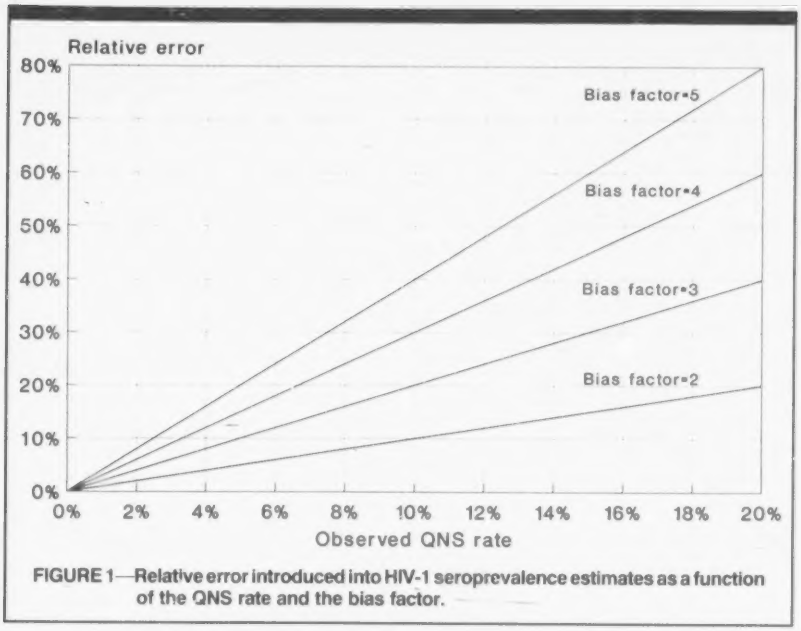

FIGURE 1—Relative error introduced into HIV-1 seroprevalence estimates as a function of the QNS rate and the bias factor.

equal to 5. Thus, minimizing QNS rates is crucial to the reduction of relative error resulting from sampling that is biased by QNS specimens.

The alternate method we describe is only marginally more labor-intensive compared with the standard method. In Wisconsin, it is estimated that the additional time required to sample QNS specimens instead of disregarding them is approximately 1 hour per 100 QNS specimens (Gary L. Hoffman, unpublished data). In other states, the additional time required to punch specimens using the alternate method will vary, depending on the number of QNS specimens and the methods used to punch specimens.

Since 1988, HIV-1 seroprevalence surveys that use dried neonatal blood specimens have become a major component of the national effort to track the epidemic of HIV-1 infection. These important studies are being relied on to reveal trends in HIV-1 infection among childbearing women and to estimate the incidence of vertically transmitted HIV-1 infection in the United States. Information obtained from these surveys can be used in planning activities to evaluate the need for and effectiveness of specific HIV-1-related prevention programs and to anticipate future demand for HIV-1-related medical and social services. Because the decisions derived from these activities are important, every effort must be made to understand and eliminate bias that may affect the accuracy of HIV-1 seroprevalence estimates. The QNS effect is but one of several potential biases inherent in these surveys.[16]

Using multiple 1/8-in blood spots to sample dried neonatal blood specimens that are of insufficient quantity to analyze using standard 1/4-in blood spots can be an effective way of ensuring the accuracy of HIV-1 seroprevalence estimates. Thus, public health agencies and laboratories involved with surveys to estimate HIV-1 seroprevalence among childbearing women in other states and regions may wish to incorporate the use of multiple 1/8-in blood spots into their survey protocols. □

The Disclosure of Celebrity HIV Infection: Its Effects on Public Attitudes

Seth C. Kalichman, PhD, and Tricia L. Hunter

ABSTRACT

Objectives. **Despite the magnitude of the acquired immunodeficiency syndrome (AIDS) epidemic, studies have shown low levels of public concern about human immunodeficiency virus (HIV)/AIDS. We investigated the effects of celebrity disclosure of HIV infection on the AIDS-related perceptions of urban men.**

Methods. **Measures of AIDS-related perceptions were collected from 361 men waiting for mass transportation in downtown Chicago; 252 were assessed at three time points prior to and 109 were assessed at two time points after professional basketball star Earvin "Magic" Johnson's disclosure of his HIV infection.**

Results. **Significant increases in concern about AIDS, interest in AIDS information, and talking with friends about AIDS occurred after celebrity disclosure of HIV infection.**

Conclusions. **Celebrity disclosure of HIV seropositivity demonstrated a marked change in AIDS-related perceptions among the men surveyed. Changes in awareness due to celebrity disclosure may lead to increased readiness to reduce risk and could be viewed as a window of opportunity for HIV prevention efforts. (*Am J Public Health.* 1992; 82:1374–1376)**

Introduction

More than 135 000 persons in the United States have died from complications of acquired immunodeficiency syndrome (AIDS), 209 000 have been diagnosed with AIDS,[1] and more than 1 million are believed to be infected with the human immunodeficiency virus (HIV).[2] Heterosexually contracted HIV has increased by more than 8% from 1991 to 1992.[1,3] However, public perceptions about HIV/AIDS have not paralleled the magnitude of the epidemic. Surveys have shown a lack of concern about AIDS among the general public.[4–8] Consequently, the social climate in the United States has not facilitated population-wide HIV-risk reduction.

One potential agent of change in the social climate regarding AIDS is disclosure of celebrity HIV seropositivity. If we assume that identification with a target celebrity results in personal relevance, the disclosure of a celebrity's HIV seropositivity should affect one's self-perceived susceptibility. A recent occurrence of just such an event afforded us the opportunity to investigate this hypothesis. In a national press conference on November 7, 1991, basketball star Earvin "Magic" Johnson disclosed that he was HIV seropositive.[9] The present study investigated the effects of Johnson's self-disclosure on the AIDS-related perceptions of urban men.

Methods

Study Design

To conduct a community assessment of men's perceptions of HIV/AIDS, we collected data at main arteries of the mass transit system in Chicago, which ranks eighth in reported AIDS cases among U.S. metropolitan areas.[1] Data were collected in the summer and fall of 1991 (n = 169), and 10 and 5 days before Magic Johnson's disclosure (on October 28 [n = 58] and November 2 [n = 25], respectively), providing three baseline data points; data were also collected 3 and 10 days after Johnson's disclosure (on November 10 [n = 49] and November 16 [n = 60], respectively), with questions added to assess specific knowledge about his self-disclosure.

Measures and Procedure

Measures were derived from questions related to risk perceptions, interest in AIDS information (see Table 1), frequency of talking with friends about AIDS, and risk behavior histories. All questions were reviewed for content and clarity by an HIV health educator and were pilot tested prior to the study.

Men were approached as they waited for mass transportation. Asked to complete surveys about AIDS, potential subjects were told that the survey would take approximately 10 minutes, could be completed while they waited for their train, and contained personal and sensitive questions. Those agreeing to participate were provided with both a survey attached to a clipboard and a pencil. After returning the survey, participants were given a flyer that described the study, pro-

vided accurate information about HIV/AIDS transmission, and included a phone number for further information. Participants were also compensated with a city mass transit token.

Sample Description

Of the 435 men who were approached, 361 (83%) participated. The respondents were 28.8 years of age (SD = 8.0); 94% completed high school; 42% reported an annual income of less than $10 000; 55% were African American; 84% were unmarried; 51% had two or more sexual partners in the past year; 7% had histories of injection drug use; 12% had sexual partners who used injection drugs; 23% had had sex with a prostitute; 19% had had homosexual contact; 32% had a history of a sexually transmitted disease; 33% had been tested for HIV antibodies; and 7% were HIV seropositive. Nonparametric and parametric statistical tests did not show any differences in sample characteristics across the five assessment points. Although it cannot be assumed that the participants are representative of men living in Chicago, their demographic characteristics approximate those of Chicago urban communities with high AIDS incidence rates.[10,11]

Results

Analyses of variance on the five assessment times with respect to AIDS-related perceptions indicated significant differences in concern over an acquaintance getting AIDS (F [4, 353] = 3.23, $P < .01$); the assessment taken 3 days after Johnson's disclosure demonstrated greater levels of concern than all three baseline points, and the assessment taken 10 days after showed greater concern than two of the baseline points. Self-concern and self-estimated risk of HIV infection also showed a similar pattern of increased concern but were not statistically significant (see Table 1).

Interest in getting more AIDS information changed significantly from baseline to postdisclosure (F [4, 341] = 2.96, $P < .02$). Of men assessed 3 and 10 days after disclosure, 58% and 56%, respectively, were very interested in getting more AIDS information, as compared with 42%, 38%, and 32% of men at the three successive baseline assessments (see Table 1). Similarly, men were more likely to discuss AIDS with friends after the disclosure (χ^2 [4] = 10.89, $P < .03$) (see Figure 1).

TABLE 1—Mean (SD) for Perceived Susceptibility and Interest Variables across Assessment Times before and after Magic Johnson's Self-Disclosure

	Before Disclosure			After Disclosure		95% Confidence Interval
	6 Months	10 Days	5 Days	3 Days	10 Days	
I am concerned that I will get AIDS[a]	2.36 (1.13)	2.38 (1.02)	2.48 (.96)	2.63 (1.11)	2.65 (1.04)	2.35, 2.57
I am concerned that someone I know will get AIDS[a]	2.84 (1.07)	2.77 (.99)	2.68 (.95)	3.27 (.94)	3.15 (.94)	2.83, 3.04
What is your risk for getting the AIDS virus?[b]	2.35 (1.11)	2.24 (.99)	2.28 (.98)	2.35 (1.07)	2.78 (1.24)	2.28, 2.52
How interested are you in getting more information about AIDS?[c]	3.21 (.84)	3.13 (.84)	3.04 (.89)	3.52 (.65)	3.44 (.77)	3.19, 3.36

[a]Ratings on a 4-point scale: 1 = not true for me; 4 = very true for me.
[b]Ratings on a 5-point scale: 1 = no risk at all; 5 = extremely high risk.
[c]Ratings on a 4-point scale: 1 = not at all interested; 4 = very interested.

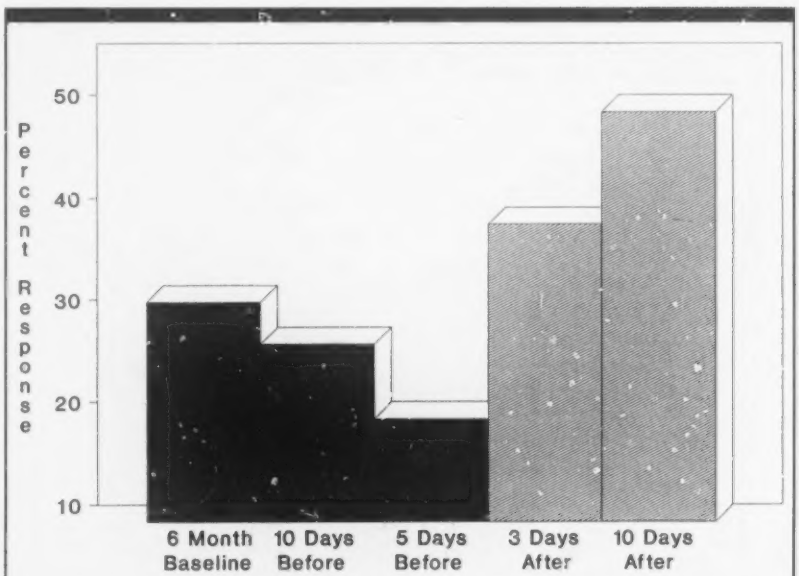

FIGURE 1—Percentage indicating that they "often" talked with friends about AIDS, across five assessment points.

All men surveyed at both postdisclosure assessments indicated that they had heard about Magic Johnson. While 86% had discussed the disclosure 3 days after, 100% had talked about it by 10 days after. Comparisons between African-American and Caucasian men showed no differences in talking with friends about the disclosure. However, significant differences were found on the question "Are you more concerned about AIDS since hearing about Magic Johnson?" (Measurement was taken using a 4-point scale ranging from "Not at all" to "Much more concerned.") African-American men indicated that Johnson's disclosure increased their concern about AIDS to a greater extent than did Caucasian men both 3 days after (t[30] = 4.25, $P < .01$) and 10 days after (t[35] = 3.43, $P < .01$) (see Figure 2).

Discussion

The shift in social climate identified in the present study appears to be a function of Magic Johnson's self-disclosure, although lack of experimental control does

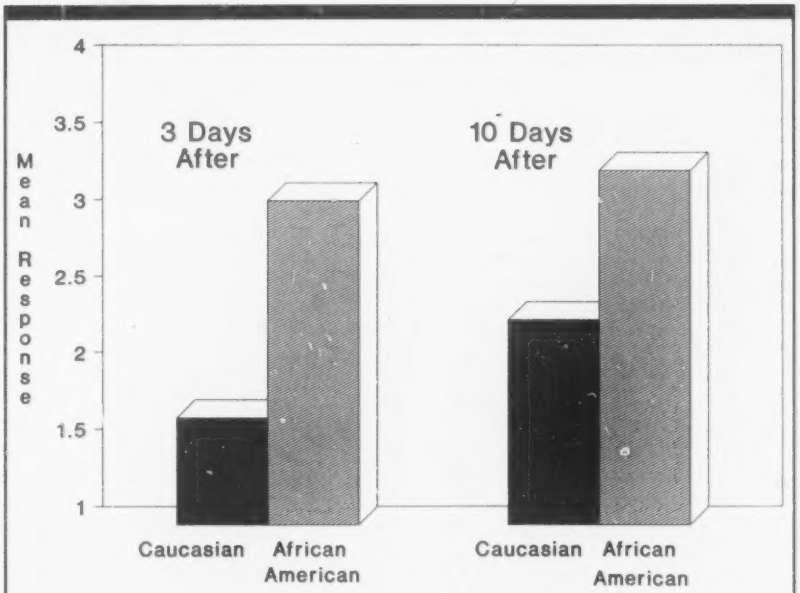

FIGURE 2—Mean responses for Caucasian and African-American men reflecting the impact of Magic Johnson's disclosure on their concern about AIDS.

not allow for the exclusion of alternative causal factors. Substantially more African-American men than Caucasian men indicated that the disclosure influenced their concern about AIDS. Because mental representations of persons afflicted with a health problem are related to their perceptions of susceptibility,[12] the impact of celebrity disclosures may vary across subpopulations, depending on group associations with the target celebrity.

The impact of celebrity disclosures on urban men's perceptions sets the stage for risk-reducing behaviors. We conclude that Magic Johnson's self-disclosure caused some men to shift from precontemplation toward contemplation of self-change.[13,14] With continued awareness and information, men may engage in self-reevaluation processes that ultimately inspire behavioral changes.[13] Thus, disclosure of celebrity HIV seropositivity provides a natural enhancement for AIDS prevention messages. Given the likely, albeit unpredictable, occurrence of such disclosures in the future, prevention programs would do well to capitalize on their immediate impact. For example, concentrated education and prevention campaigns may be prepared in advance and held until a celebrity disclosure occurs. Additionally, further research is needed to understand better the link between celebrity disclosure and risk perceptions, as well as the relationship between any resultant change in the social climate and changes in risk behavior. Finally, social risks should be minimized to encourage disclosure, and celebrity messages should be tailored to maximize their social impact. □

Legal Blindness among 10-Year-Old Children in Metropolitan Atlanta: Prevalence, 1985 to 1987

Carolyn D. Drews, PhD, Marshalyn Yeargin-Allsopp, MD, Catherine C. Murphy, MPH, and Pierre Decoufle, ScD

ABSTRACT

The prevalence of legal blindness in 10-year-olds in metropolitan Atlanta was 6.8 per 10 000 during 1985 to 1987. The prevalence was 8.8 per 10 000 in Black boys, 8.6 per 10 000 in White boys, 6.7 per 10 000 in White girls, and 1.8 per 10 000 in Black girls. Retinopathy of prematurity was the most common known cause (1.0 per 10 000). Of the 61 cases, 40 had other disabilities, including 14 with mental retardation, cerebral palsy, and epilepsy. The low prevalence among Black girls and the frequent occurrence of blindness with other disabilities are noteworthy. (*Am J Public Health.* 1992;82:1377–1379)

Introduction

There is a lack of current data on the prevalence of childhood blindness in the United States. This paper examines three aspects of childhood blindness in Atlanta during 1985 to 1987: its prevalence, causes, and association with other developmental disabilities.

Materials and Methods

The Metropolitan Atlanta Developmental Disabilities Study estimated the prevalence of five developmental disabilities in 10-year-olds living in five metropolitan Atlanta counties during 1985 to 1987.[1]

Blind children were identified by reviewing records at public schools, hospitals, health and mental health service agencies, and public and private social service agencies. Blindness was defined as a best corrected visual acuity of 20/200 or worse in the better eye[2] or a statement by a trained person (i.e., ophthalmologist or optometrist) that the child was blind, since measuring visual acuity in young children, especially those with other disabilities, is often difficult. Age at documentation is defined as the earliest age at which records available to us stated that the child was blind or had a best corrected visual acuity of 20/200 or worse.

Etiology was defined as the underlying condition that led to blindness. Etiology was considered to be unknown if an underlying condition could not be determined from the available records even if the child was at high risk for blindness (e.g., due to prematurity). Age at onset was defined as the age at the time of the presumed etiologic event.

Prevalence rates and their 95% confidence intervals (CI) are reported per 10 000 10-year-olds.[3] Using data provided by the Georgia Office of Planning and Budget, we estimated that 89 534 ten-year-olds lived in Atlanta during 1985 to 1987. Race was defined as White or Black since all cases were either White or Black and 96% of children in Atlanta who are not White are Black.

Results

We identified 61 blind children (6.8 per 10 000) (Table 1). The prevalence of blindness was slightly higher in Whites than in Blacks but was higher in boys than in girls. However, the magnitude of the gender difference varied substantially by race.

Retinopathy of prematurity was the most common known cause of blindness (1.0 per 10 000; 95% CI = 0.5, 1.9) (Table 2). Thirteen children had an eye malformation. Two other children had cataracts resulting from prenatal infections. Thus, one quarter (15) of the cases were known

[f]Blindness due to congenital glaucoma in one eye and myopia in the other.
[g]No information available on the etiology of blindness.

to have an eye malformation. Information on etiology was missing for eight cases.

Two thirds (39) of the cases had the condition that blinded them by the time they were 1 month old, but few were documented to be blind in infancy (Table 3).

Two thirds of the cases had at least one of four other disabilities; 40% (25) had at least two (Table 4). Fourteen (23%) children had mental retardation, cerebral palsy, and epilepsy (1.6 per 10 000; 95% CI = 0.9, 2.6).

Discussion

The prevalence of blindness in 10-year-olds in Atlanta is slightly higher than previously reported rates for developed countries (3.4 to 6.2 per 10 000).[4-8] Variations in the reported rates may be due to instability of rates based on small numbers or may represent real differences in occurrence, especially if survival of high-risk infants differs. Differences in ascertainment methods may also create apparent differences in prevalence rates. Cases may be underascertained if identified solely through schools for the blind or through blindness registries since these programs are usually voluntary.[4] Only 6 of 61 cases in this study had attended schools for the blind; 21 of the children with multiple disabilities had attended special education programs that were not designed specifically for blind children.

As in other studies, boys were more likely to be blind than girls.[5,6,8,9] However, six of the nine children with retinopathy of prematurity were girls. This finding could be due to small numbers, better survival of low-birthweight girls than boys,[10] or gender-based differences in birthweight.[6]

The overall prevalence of blindness was slightly higher in Whites than in Blacks, but the pattern differed by gender. Reasons for this finding are not clear, and the rates are based on small numbers. Few previous studies have reported race-specific or race-and-sex-specific rates of childhood blindness. An early study found that the prevalence was 20% lower among Whites than among other races, but the rates were not presented by gender.[4]

The low prevalence of blindness among Black girls is striking and should be confirmed in other populations. Ascertainment could differ by race or socioeconomic status but should not vary by gender. Thus, we do not believe that we have undercounted cases among Black girls. The prevalence might be low in Black girls if they are less likely to have conditions that put them at risk of blindness or if those at high risk are less likely to survive than other children.

As in previous studies, about two thirds of our blind children had other disabilities.[7,9,11] Blindness, mental retardation, epilepsy, and cerebral palsy occurred with an unexpectedly high frequency in this population. The occurrence of this combination of disabilities should be examined in other populations.

In earlier studies, 7% to 14% of blind children were hearing impaired, with most cases attributed to rubella.[8,9,11] In contrast, only three (5%) of our cases were hearing impaired; one case was attributed to congenital rubella syndrome. Thus, rubella appears to be a less important cause of blindness among children born in the mid-1970s than in previous birth cohorts.[12]

Our results underscore the concern that improved survival of low-birthweight infants may increase the prevalence of

Mental retardation, epilepsy, cerebral palsy, and hearing impairment	0	...

blindness due to retinopathy of prematurity since this condition accounted for 15% of our cases.[13–17]

Most of the conditions that caused blindness originated prenatally, and one quarter of the blind children had a congenital eye defect. These proportions might have been higher if our data on etiology had been more complete. However, most cases of blindness were first documented after age 4. The lag between age at onset and documentation may be related to our methodology or difficulties in measuring vision in very young children, and does not necessarily indicate a delay in treatment of childhood visual impairments. These findings emphasize the importance of early intervention and of identifying ways to improve the visual outcome of children born with conditions that put them at risk of being blind. □

Sudden Infant Death Syndrome and Maternal Smoking

Michael H. Malloy, MD, MS, Howard J. Hoffman, MA, and Donald R. Peterson, MD, MPH

ABSTRACT

Data from Missouri for the period 1980 to 1985 suggest a dose–response relationship between smoking during pregnancy and the incidence of sudden infant death syndrome (SIDS). However, data from the National Institute of Child Health and Human Development SIDS Cooperative Epidemiological Study did not support a dose–response relationship. Neither the Missouri data nor the Cooperative Study data support a relationship between the age of occurrence of SIDS and smoking during pregnancy. (*Am J Public Health.* 1992;82:1380–1382)

Introduction

A number of socioeconomic and demographic factors are associated with an increased risk of sudden infant death syndrome (SIDS), but few readily amenable exposure factors have been identified.[1] Reports of an association between maternal cigarette smoking during pregnancy and the subsequent occurrence of SIDS, however, do offer the possibility that reducing maternal smoking could result in a decline in the SIDS rate.[2–4] Whether the association between SIDS and a history of maternal smoking during pregnancy is biological in nature or a proxy for maternal behavior is not clear. Haglund and Cnattingius reported that infants born to women who smoke during pregnancy die earlier with SIDS than infants of nonsmokers and that a dose–response association exists between maternal smoking and the risk of SIDS.[5] Their report supports the plausibility of a biological mechanism. We attempted to confirm their observations in two large US data sets.

Methods

The Missouri data set is a linked birth and death certificate file for the period 1980 to 1985. There were 684 SIDS deaths in Missouri during this period. Complete data were available on 636 of these cases and 425 326 live births, an overall rate of 1.6/1000 live births (1.3 non-Black vs 3.1 Black). For this analysis, we excluded infants of gestational age less than 24 weeks or greater than 45 weeks and excluded cases of SIDS in which the age of death was less than 7 days. Seventy-six percent of the SIDS deaths reported between 1980 and 1985 were autopsied, but no other special review process was carried out to confirm the validity of the assignment of the diagnosis of SIDS. Additional information obtained from the birth certificate included race, maternal age, parity, maternal education, and marital status. Maternal smoking information was obtained from the birth certificate and was reported in terms of packs of cigarettes smoked per day.

The National Institute of Child Health and Human Development SIDS Cooperative Epidemiological Study was a case-control study conducted between October 1978 and December 1979 that accrued cases of SIDS across six geographic regions.[6] The SIDS rate for this study was 1.75/1000 live births (1.10 non-Black vs 3.65 Black). All cases of SIDS were autopsied, and a panel of three expert pathologists reviewed each of the cases to determine the reliability of the diagnosis. Living controls (Control A) were selected from regional birth certificate files to match regional cases on the age of death. A second living control (Control B) was matched to the SIDS case within each region on age, race, and birthweight (≤2500 g). There were 757 SIDS cases and 1514 controls available for this analysis. Mothers of SIDS cases were interviewed 2 to 5 weeks after the child died. Mothers of cases and controls were asked during the interview how many cigarettes per day they smoked during the first, second, and third trimesters. For this analysis, information on smoking in the first trimester was used.

Analyses were carried out to determine whether the SIDS infants' age of death was less when the mother smoked than when the mother did not smoke by using general chi-square tests of association. The relationship between the quantity smoked and infant mortality was analyzed by logistic regression.[7] Two-way interactions between smoking and covariates in the logistic models were exam-

ined, but none were significant. Analyses were done with SAS.[8]

Results

In the Missouri population and in the Cooperative Study, the distribution of the age of SIDS death for smokers and nonsmokers appears quite similar (Figures 1 and 2). There were no statistically significant associations by general chi-square analysis. The median age of death for both nonsmokers and smokers was 11 weeks. This contrasts with the observation from Sweden of a median age of SIDS death among nonsmokers of 10.4 weeks compared with 8 weeks among smokers.[5]

The dose–response relationship between smoking and SIDS was examined by logistic regression (Table 1). The odds ratios were adjusted by logistic regression for race, parity, age of the mother, maternal education, marital status, and sex of the infant. For Missouri, the adjusted odds ratios were 1.98 for light smokers compared with nonsmokers and 2.86 for heavy smokers compared with nonsmokers. The odds ratio for heavy smokers compared with light smokers was 1.41 with a 95% confidence interval (CI) that did exclude 1.0.

For the Cooperative Study, the adjusted odds ratios, with the reference group being nonsmokers and using Control A (the controls matched on age alone), were 2.49, 3.24, and 3.05 for smokers of less than 10, 10 through 19, and 20 or more cigarettes per day, respectively. For Control B (the controls matched on age, birthweight, and race), the odds ratios were 2.68, 2.65, and 2.60, respectively.

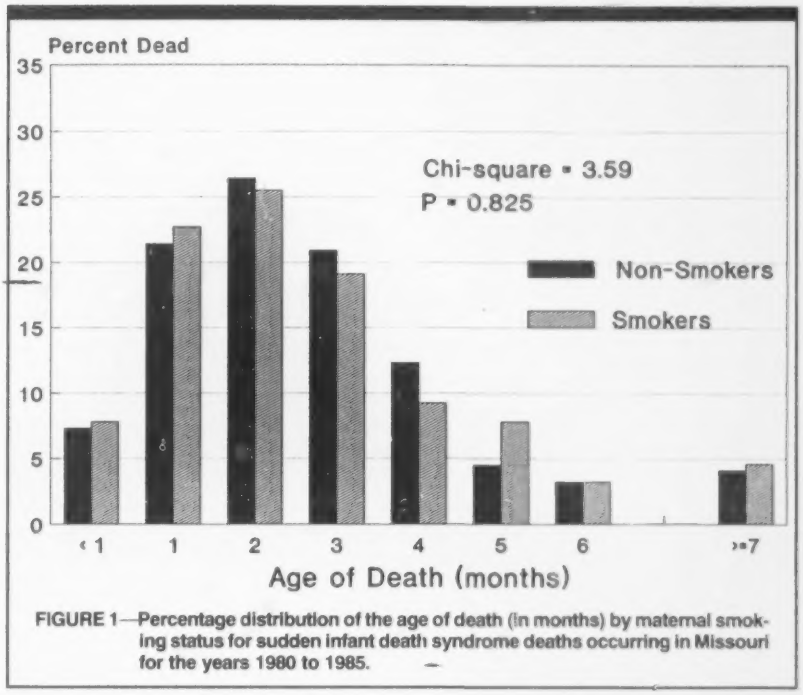

FIGURE 1—Percentage distribution of the age of death (in months) by maternal smoking status for sudden infant death syndrome deaths occurring in Missouri for the years 1980 to 1985.

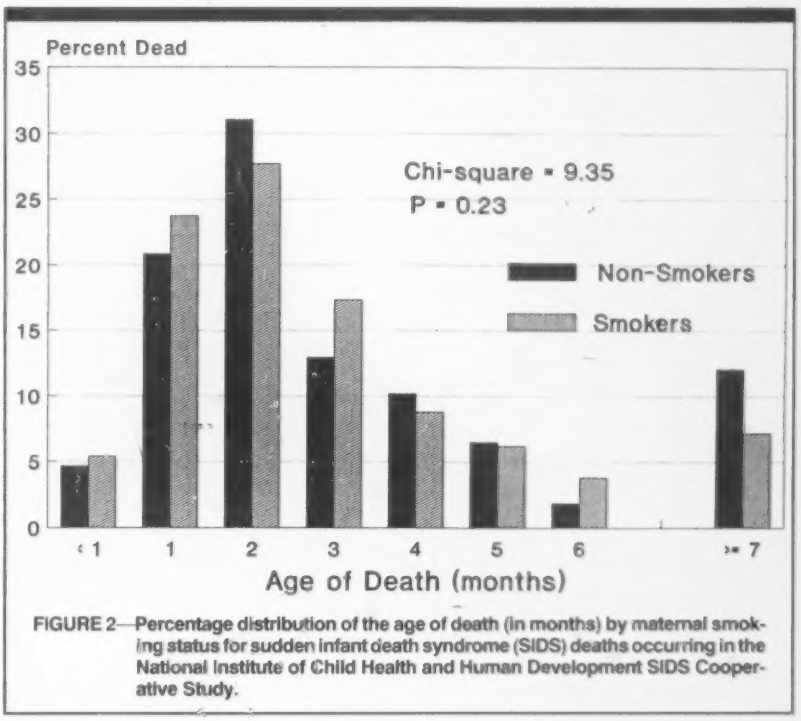

FIGURE 2—Percentage distribution of the age of death (in months) by maternal smoking status for sudden infant death syndrome (SIDS) deaths occurring in the National Institute of Child Health and Human Development SIDS Cooperative Study.

Discussion

We were unable to confirm the Swedish observation of a relationship between the age of death and a history of maternal smoking during pregnancy. In the Missouri population, we did observe a relationship between the quantity smoked and the risk for SIDS. Data from the Cooperative Study, however, failed to support a dose–response relationship. Differences in results between the two populations may be due to recall bias. In the Cooperative Study women reported smoking after the death of the infant, while in the Missouri population smoking information was reported on the birth certificate prior to the death of the infant. However, the direction of this potential bias is uncertain.

Confirmation of the Swedish report of an earlier age of death among infants of smokers would support the hypothesis that the relationship between maternal smoking and SIDS is biologic. However, we were unable to demonstrate this relationship with two large US data sets. Nevertheless, further research into biologic mechanisms and life-style factors by which maternal smoking might increase the risk of SIDS should be pursued.

TABLE 1—Adjusted Odds Ratios[a] for Sudden Infant Death Syndrome (SIDS) from the Missouri and NICHD[b] SIDS Cooperative Epidemiological Study Populations

Population/No. of Cigarettes Smoked Daily	Adjusted Odds Ratio	95% CI
Missouri		
Nonsmoker	1.00	...
<1 pack	1.98	1.64, 2.41
≥1 pack	2.86	2.32, 3.50
≥1 pack vs <1 pack	1.41	1.13, 1.76
Cooperative study		
Control A		
Nonsmoker	1.00	...
<10	2.49	1.79, 3.46
10–19	3.24	2.31, 4.55
≥20	3.05	2.24, 4.15
Control B		
Nonsmoker	1.00	...
<10	2.68	1.94, 3.71
10–19	2.65	1.91, 3.67
≥20	2.60	1.93, 3.52

[a]Odds ratios adjusted for maternal age (< 20 vs ≥20 years), race (Black vs non-Black), parity (≥2 vs <2), educational status (<12 vs ≥12 years), marital status (single vs married), and sex of the infant.
[b]National Institute of Child Health and Human Development.

Public health programs that encourage smoking reduction for pregnant women offer the possibility of effecting a more immediate decline in SIDS. It remains to be determined, however, whether the benefits of public health programs that encourage smoking reduction will include a decline in SIDS occurrence. □

Acknowledgments

An abstract of this research was presented at the April 1991 joint annual meeting of the American Pediatric Society and the Society for Pediatrics Research in New Orleans, La.

We would like to thank Garland Land and his staff at the Missouri Department of Health for making vital statistics data available for this research study. Also, we would like to acknowledge the principal investigators and their staffs, including the scientific advisors and consultants, of the National Institute of Child Health and Human Development SIDS Cooperative Epidemiological Study.

Call for Historical Papers on Public Health Nursing

Because in 1993 public health nurses celebrate their centennial, historians of public health nursing are invited to submit articles for review for centennial publications planned by the journal *Public Health Nursing.* Guidelines for authors are printed in the back cover of the journal. Issues are published in March, June, September, and December, and deadlines are 6 months prior to publication. For additional information, please call Karen Buhler-Wilkerson, historical editor, *Public Health Nursing,* at (215) 898-4725.

Stage at Diagnosis in Breast Cancer: Race and Socioeconomic Factors

Barbara L. Wells, PhD, and John W. Horm, MSc

ABSTRACT

Cancer incidence data from three US metropolitan areas were coupled with census tract indicators of education and income. The data suggest that both Black and White cancer patients living in census tracts with lower median education/income values are diagnosed in later disease stages than are patients in tracts with higher median education/income values. Within education and income strata, Black women had a less favorable stage of disease at diagnosis than Whites. The exception was in upper education/income levels, where the disadvantage for Blacks disappeared. These data provide additional evidence that women of low socioeconomic status could benefit from targeted screening. (*Am J Public Health.* 1992;82:1383–1385)

Introduction

Breast cancer has the highest incidence of any cancers among both Black and White women,[1] with about 181 000 new cases expected in 1992.[2] Although the incidence is higher among White women, breast cancer mortality is substantially greater among Black women,[3,4] reflecting their poorer survival experience.[3,5] Survival has differed by income[6] and socioeconomic status level, even when stage adjusted.[7] Stage at diagnosis strongly influences breast cancer survival and, in the few studies investigating socioeconomic status *and* stage at diagnosis, women of lower socioeconomic status with breast cancer were more likely to be diagnosed at a later stage.[8] In comparisons between Black and White women, proportional differences of metastatic breast cancer have been the greatest with the largest differences in income.[9] When Black–White differences in socioeconomic status are small, there are small differences in the distribution of stage at diagnosis.[10] We extend these smaller studies with data from a large population-based set of tumor registry data to investigate the effect of socioeconomic status on Black–White differences in stage of disease at diagnosis and the impact that levels of socioeconomic status have on stage distribution within race.

Materials and Methods

This study used the population-based incidence data, including stage of disease at diagnosis, from the US National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) Program. The SEER Program collects information on all cases of cancer diagnosed among geographically defined subsets of the US population.[1,11] Median values for education and family income at the census tract level were obtained from the 1980 US census and matched with SEER data. Cancers diagnosed from 1978 to 1982 were included to center around the census. The San Francisco–Oakland, Detroit, and Atlanta metropolitan areas were used for two reasons: they are census tracted and therefore could be matched with census tract indicators of socioeconomic status, and they have sufficiently large numbers of Blacks for analysis.

There were 18 113 White and 2861 Black cases of invasive breast cancer reported in the three areas during our study period that could be matched with a census tract (2.1% of the total number of breast cancers could not be matched). Of these, 187 cases were incidental diagnoses at autopsy or the only evidence of their breast cancer was the death certificate with no indication of a prior diagnosis. After excluding these cases, 17 949 invasive breast cancer and 917 in situ cases among White women, and 2838 invasive and 126 in situ cases among Black women, were available for analysis.

The median family income strata were chosen so that each had enough persons of each race for meaningful analysis; $15 000 also was approximately twice the poverty level for a family of four in 1979.[12] Race-specific indicators of median education and family income were used because Whites and Blacks living in the same census tract may have different education and/or income distributions.

The in situ and localized disease stages used here are defined as confined to the site/organ of origin, with the former not being able to metastasize. Cases spread by direct extension to adjacent organs/structures or to regional lymph nodes are considered regional stage. Distant stage includes disease cases involving distant organs or lymph nodes either by direct extension or through discontinuous metastasis.[13] The "other" stage contains those cases that could not be staged from the information contained in medical records or were otherwise unclassified.

Note. The results of the Spearman rank-correlation test of association between education and stage of disease were as follows: Black, $t = -4.02$, $P < .001$, and White, $t = -3.86$, $P < .001$.
[a]The three areas are San Francisco–Oakland, Detroit, and Atlanta.

To test the relationship between stage of disease at diagnosis and income/education, the Spearman rank-correlation coefficient was computed.[14]

Results

Our data indicate that Black women with breast cancer are diagnosed at a later stage of disease than are White women. Only 45.7% of Black women diagnosed in the more curable localized and in situ stages compared with 52.1% of White women (Table 1). Over 11% of the Black women and less than 7% of Whites had breast cancers that had already metastasized beyond localized or regional into distant stage.

Among both Black and White women, there is a tendency toward a less advanced stage with increasing educational level or income ($P < .001$) (Tables 1 and 2). The percentage of cases with distant disease decreases with increasing educational level or income among women of both racial groups.

Black women in both of the two lowest educational strata and income strata had a poorer stage of disease at presentation than did White women. This pattern was not present in either the upper educational strata or the upper income strata. In each of these two strata, Black women had a slightly better stage of disease at diagnosis than did White women.

The incidence of breast cancer is higher among both Black and White women in the upper education and income categories (Tables 3 and 4). This appears largely due to higher rates in the in situ and localized stages. In the distant stage, however, the pattern is the opposite for both races: incidence decreases with increasing education and income. The differences between educational and income strata are more striking among Black women.

Discussion

The association between female breast cancer stage at diagnosis and socioeconomic status gives credence that those of lower income/education are less likely to participate in breast cancer early detection. This lack of participation is further supported by 1987 National Health Interview Survey findings.[4,15] People in lower income/education strata were less likely to have had a screening mammogram within the past year (9.2% with incomes of less than $10 000, 20.9% with incomes of more than $35 000) and were less likely to have heard of the test (24.6% vs 5.9%). Thus, it appears that the most immediate and practical implication of this investigation's results is that cancer screening programs are especially appropriate in populations of lower socioeconomic status, particularly among Blacks.

Offering breast cancer screening programs to those of lower socioeconomic status and Blacks is not without challenges, however. Women of lower socioeconomic status have less access to preventive and medical care, and asymptomatic persons of lower socioeconomic status may not make optimal use of preventive health services.[16–19]. Among Blacks, there may be even less use of the medical system, as compared with Whites.[20] Office visit and screening procedure costs are reported barriers by many Black women,[21] as are physicians' failure to discuss mammography with women and women's perceptions of breast cancer and screening.[22] This complex assortment of challenges requires that early detection barriers of a population be precisely identified to design and maximize effective interventions. □

Measuring the Use of Mammography: Two Methods Compared

Darrah Degnan, BSc, Russell Harris, MD, MPH, Jane Ranney, PhD, Dana Quade, PhD, Jo Anne Earp, ScD, and Jorge Gonzalez, MD

ABSTRACT

Population studies often estimate mammography use using women's self-reports. In one North Carolina county, we compared self-report surveys with a second method—counting mammograms per population—for 1987 and 1989. Estimates from self-reports (35% in 1987, 55% in 1989) were considerably higher than those from mammogram counts (20% in 1987, 36% in 1989). We then confirmed 66% of self-reports in the past year. Self-reported use is more accurate regarding whether a woman has had a mammogram than when she had it, but self-reports accurately measure change over time. (*Am J Public Health.* 1992;82:1386–1388)

Introduction

A number of studies have examined the percentage of women in the population receiving mammograms.[1–4] Most of these studies rely on self-reported behavior, subject to the errors of this method.[5–7]

We collected self-report data on mammography use by a random-digit dialing telephone survey in a single county of North Carolina.[2] Using institutional records, we also documented mammograms performed on county residents for 1987 and 1989. This paper compares these two methods of measuring mammography use.

Methods

This study was approved by the Committee on the Protection of Human Subjects of the University of North Carolina School of Medicine.

Site and Population Characteristics

The total population of New Hanover County, NC, is 120 000, with about 14 000 women aged 50 to 74 years.[8] Because New Hanover contains a regional medical center and is geographically isolated, nearly all county residents use local sources of medical care.

Data Sources

Telephone survey self-reports. In January 1988 and 1990, we conducted 15-minute random-digit dialing telephone interviews with county women aged 50 to 74 years. Women were asked, "Have you ever had a mammogram?" and "How long ago did you have your last mammogram?" The telephone response rates were 73% (n = 487) in 1988 and 74% (n = 486) in 1990. Respondents were invited to give their names for follow-up; 85% did so.

Mammogram counts from institutional records. From all radiology centers, we obtained logbook or computer report listings of all county women who had had mammograms in 1987 and 1989, and we collected a copy of the mammogram reports. Data (name, age, social security number, zip code, date of mammogram) from all centers were combined into a single database. Women not aged 50 to 74 years and out-of-county residents were excluded. We then divided the number of county women who had had a mammogram by the number of all county women aged 50 to 74, using population estimates from the North Carolina Office of State Management and Budget.

Validating January 1990 Self-Reports against Institutional Records

We supplemented the 1987/1989 mammogram listings with listings from 1988 and January 1990. We matched "self-report" women by date of birth and name with their most recent mammogram in the expanded database. We confirmed matches by comparing the self-reported telephone numbers with those on the mammogram reports. To verify the identity of women not matched, we used telephone numbers from public directories. We also searched institutional databases for women not matched, both those reporting and those denying a past-year mammogram. We did not attempt to verify reports of women who claimed mammography outside the county (n = 19).

Analysis

We calculated the proportion of women who reported having had a mammogram for 1987 and 1989. We used linear regression to estimate the relationship between reported months and actual months

TABLE 1—Verification of Mammogram Self-Reports of Women Aged 50 to 74 Years in New Hanover County, North Carolina, 1989

Self-Reported Date of Most Recent Mammogram	Actual Date of Mammogram Confirmed by Mammogram Report: Within Past Year	More Than 1 Year Ago; Not More Than 2 Years Ago	More Than 2 Years Ago	No Report Found	Total
Within past year	164	58	8	17[a]	247
More than 1 year ago but not more than 2 years ago	1	22	11	5	39
More than 2 years ago	0	0	5	12	17
None	1	0	0	152	153
Total	166	80	24	186	456

[a]Includes two who had chest X-rays and eight whose identity could not be independently verified.

since the last mammogram. We used the χ^2 statistic to relate the accuracy of the self-report to age, education, employment, and income groups.

Results

In January 1988, 35% of interviewed women reported having had a mammogram in the past year; this increased to 55% in 1990.[9] The mammogram counts from institutional records were 2650 (20% of the population of 13 501) for 1987 and 4994 (36% of population of 14 025) for 1989.[9] After excluding 19 women who reported a past-year mammogram but outside the county, we matched mammogram records in 1989 for 164 of the remaining 247 women (66%) interviewed in January 1990 who reported a past-year mammogram in the county (Table 1). The 164 confirmed self-reports totaled 34% of the initial survey sample (n = 486), compared with 36% of the same population found by counting mammograms (Figure 1).

Incorrect recollection of the date—actually longer than past-year—was more common (66/247 or 27%) than unconfirmed reports (17/247 or 7%). The regression line equation for plotting reported time since last mammogram against actual time was actual time = 2.54 + (1.02 × reported time), indicating that actual time was about 3 months longer on average than reported time. Among those denying a mammogram, one report was found. There was no statistically significant association between accuracy of self-report and age, education, employment, or income.

Discussion

Women aged 50 to 74 in one county reported higher mammography usage within the previous year than that calculated from institutional records (35% vs 20% in 1987; 55% vs 36% in 1989). Change over time was similar by both methods (20% vs 16%). Of those interviewed in 1990 who reported having had a mammogram within the county in the past year, 66% were confirmed by mammogram records. We found the overreporting by self-report was due primarily to underestimating the time since the last mammogram ("telescoping"), not to unconfirmed usage.

Although telephone interviews do not gather information about women without telephones (12% of all households) or about nonrespondents, the response rate of our survey was acceptable for a population survey,[5] and the percentage of women with validated self-reports (34%) agreed closely with usage calculated from institutional records (36%).

To our knowledge, no previous study has examined mammogram counts per population as a method of measuring mammography use. Although the mammogram count method avoids the overreporting found in the self-report method, it introduces a potential undercount if all mammograms are not located. We are confident that we located nearly all mammograms because (1) the setting made it likely that nearly all county residents would have had mammography within the county, and (2) we were able to document a mammogram of some date on all but 7% of the respondents.

Our results agree with those of Gordon et al. (personal communication, October 23, 1991), who confirmed 67% of

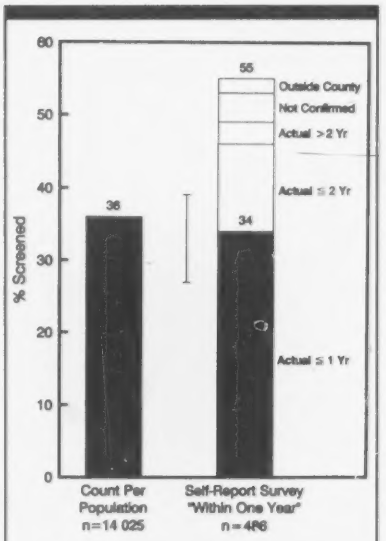

FIGURE 1—Percentage of women aged 50 to 74 screened in past year, New Hanover County, North Carolina, 1989.

reported mammograms within the previous year for women aged 50 to 74 years in a large health maintenance organization. They differ, however, from those of King et al.,[10] who verified 94% in another health maintenance organization where respondents were concurrently cued to get mammography. We agree with others[7,11,12] that the telescoping phenomenon should be taken into account in survey research.

Measuring mammography rates in a general population by self-report is accurate for determining whether a woman has had a mammogram but is less accurate for determining when. Surveys that ask "when was your last mammogram" will overestimate usage. Such surveys can, however, accurately estimate change in usage. In suitable areas, researchers can estimate usage directly by counting institutional records. □

Women with Multiple Sexual Partners: United States, 1988

Stuart N. Seidman, MD, William D. Mosher, PhD, and Sevgi O. Aral, PhD

ABSTRACT

Women who have multiple sexual partners in a short time period are appropriate targets for sexually transmitted disease (STD) prevention. We analyzed survey data collected in 1988 from a nationally representative sample of 8450 American women aged 15 to 44 to identify markers of such behavior. Among sexually active persons, 0.4% of married women and 8.4% of unmarried women had two or more sexual partners in the 3 months preceding the interview; unmarried marital status, early age at first sexual intercourse, lack of religious affiliation, and young age were associated with this behavior. All except young age were predictive after multivariate analysis. Such factors may help define women at elevated STD risk and allow better targeting of STD prevention. (*Am J Public Health.* 1992;82:1388–1394)

Introduction

Each additional sexual partner puts an individual at some incremental risk of exposure to a sexually transmitted pathogen and increases the dissemination of such pathogens. The number of lifetime sex partners quantifies an individual's cumulative risk for persistent viral sexually transmitted diseases (STDs) and cervical cancer[1–5] and is associated with bacterial STDs, including pelvic inflammatory disease.[6–8] The number of sex partners in a recent time interval, such as the previous several months, is a more precise measure for assessing the risk for incident infection: among STD clinic patients, having multiple partners in a specific recent time period (less than 6 months) is a risk factor for the acquisition of bacterial STDs, such as gonorrhea,[9,10] chlamydia,[11–13] syphilis,[14] and chancroid,[15] as well as for the presence of viral STDs.[16–18] Furthermore, for STDs with a short period of infectiousness, such as gonorrhea, having multiple partners in a short time span increases the rate of dissemination in the population.

One way to identify individuals at greatest risk is to focus on those who report having two or more partners in a specific time interval. Having multiple recent partners is associated with disease risk for at least two reasons: first, it reflects the increased likelihood of encountering a sexually transmitted pathogen through having multiple potential exposures, and second, it may reflect an increased probability of choosing a partner with an infection through a riskier pattern of partner recruitment.[19,20] Primary prevention strategies to reduce the number of sexually transmitted infections can use the characteristics of these women to target education and counseling that encourage safe sexual practices. Secondary prevention strategies, aimed at early diagnosis and treatment of asymptomatic infection, can target these high-risk women for selective screening (e.g., for human immunodeficiency virus, syphilis, and/or pelvic inflammatory disease).

Over this century, Americans have increasingly had greater numbers of sexual relationships, in part because of postponed marriage, increases in separation and divorce, and more reliable contraception.[21,22] A growing majority of unmarried

women are sexually active,[23,24] and many young women who reduce the number of sexual partners they have because of fear of acquired immunodeficiency syndrome (AIDS) continue to have more than one partner.[25] Overall, almost two thirds of sexually experienced women report having had two or more sexual partners during their lifetime,[23,24] and this proportion is increasing. These developments are likely to portend even greater proportions of sexually active women, especially young women, having multiple sexual partners.

In the 1988 through 1990 General Social Survey, a nationally representative survey that included 1123 women 18 to 49 years of age, 13% of these women reported having two or more sexual partners in the preceding year (General Social Survey, unpublished data). A combined analysis of this survey and one conducted by the *Los Angeles Times* suggests that about one fourth of unmarried women of reproductive age had two or more sexual partners in the preceding year.[21] From the General Social Survey, factors associated with a greater mean number of partners in the preceding year were young age, single marital status, and central city residence.[26] Similarly, in a self-administered questionnaire from clients of a family planning clinic in Pennsylvania, factors that were associated with women reporting five or more sexual partners in the previous year included young age, unmarried marital status, and lack of any college education.[19]

Each of the previous studies of women with multiple partners has added significantly to the demographic description of these women. However, interpretation of data from these studies is somewhat limited by methodological concerns. For example, the *Los Angeles Times* survey had a response rate of only 33%.[21] Most significantly, none addressed the prevalence of having multiple partners in a recent short time period.

The present study uses face-to-face interviews of a representative sample of American women to focus on factors associated with having multiple partners in the 3 months preceding the interview.

Methods

We obtained data for this analysis from the National Survey of Family Growth Cycle IV conducted by the National Center for Health Statistics. The National Survey of Family Growth is based on personal interviews with women of reproductive age regarding fertility, family planning, and maternal and child health. The Cycle IV survey was conducted between January and August 1988 with a multistage probability sample of 8450 women 15 to 44 years of age in the civilian noninstitutionalized population of the United States. The sample included 5354 White women, 2771 Black women, and 325 women of other races. In personal interviews lasting just over an hour, respondents provided detailed information on their reproductive health, including age at first intercourse, and number of recent sexual partners. Response rates were high overall (82.5%), and similar for Black (82.2%) and White (82.6%) women. For most of this analysis, only women who reported having had sexual intercourse in the preceding year were included. This reduced the sample size to 7011 women.

Reported percentages are weighted national estimates. The weight for each respondent represents her probability of selection for the survey, adjusted for nonresponse and adjusted again to agree with US Bureau of the Census estimates by age, race, marital status, and parity.[27] The *z* tests used in Tables 1 through 3 applied the formulas and procedures recommended for this survey.[27] These formulas are based on the balanced half-sample replication technique, an accurate method for estimating sampling errors from complex samples such as this one. These estimates take into account both the sample size and sample design on which our weighted percentages are based.

Near the end of the interview, after questions about pregnancy, contraception, and marriage, all women who had ever had intercourse were asked: "In the last 3 months in which you were having intercourse, with how many men did you have intercourse?" The variables and categories shown here were arrived at after preliminary analysis, using both cross tabulation and logistic regression. Our tables show women who report two or more partners in the preceding 3 months as a percentage of all women in a particular group who had intercourse in the previous year. Relative risks and confidence intervals were determined from these proportions for each group. To determine which variables were independently associated with having multiple recent partners when the effects of other variables were controlled, we used multiple logistic regression.

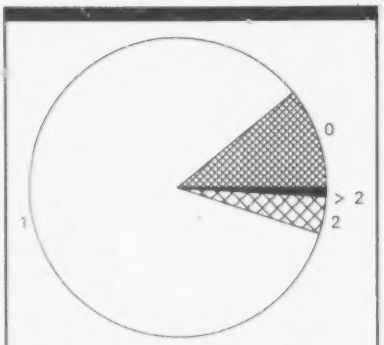

FIGURE 1—Number of recent (previous 3 months) sex partners among women 15 to 44 years of age.

Results

Overall, in 1988, 11% of all women of reproductive age did not have intercourse at all in the preceding 3 months, 85% had intercourse with one man during that period, 4% had intercourse with two men during that period, and less than 1% report having intercourse with three or more men in the preceding 3 months (Figure 1).

Of sexually active women (i.e., those who have had sexual intercourse in the preceding year), 3.4% report having intercourse with two or more men in the previous 3 months (Table 1). Marital status is the most important predictor of having two or more partners: 0.4% of married women report multiple partners in a 3-month period compared with 7.9% of never-married women and 9.5% of divorced/separated women (Table 1). Since the proportion having multiple partners is small among married women and substantially higher among never-married and divorced/separated women, and since STD incidence among Blacks and Whites differs dramatically, the results are stratified by marital status and race.

Among all sexually active women, increasing age is associated with lower proportions reporting multiple recent partners (Table 1). This is related to the greater proportion of married women in the older age groups. Among those who are not married, however, the pattern among Blacks reveals a later peak in this behavior among women in their thirties (Figure 2). Among unmarried, sexually active White women, most of those who report having two or more recent partners are under 30 years of age; the unmarried, sexually active Black women who report this most are those 30 or older. In fact, further stratification reveals that 35- to 39-year-old

divorced/separated Black women, in particular, report two or more recent partners more often than any other race–marital status group (16.4%).

Poverty status is associated with distinct patterns of this behavior among women of reproductive age overall (Table 1), but not among unmarried women in particular. In general, less education is associated with multiple recent partners among all unmarried women except divorced/separated White women. Never-married White women with a high school diploma only are significantly more likely to report multiple recent partners than those with some college education or no high school diploma (relative risk = 2.4, $P < .05$) (Table 2). Among never-married Black women, formal education is inversely associated with multiple recent partners: 9.2% of those in the lowest education group report having two or more recent partners compared with 2.7% among those with some college ($P < .05$). In contrast, among divorced/separated White women, educational level is positively associated with having multiple partners: 5.5% of those without a high school diploma, 7.3% of those with only a high school diploma, and 13.7% of those with some college had two or more partners in the preceding 3 months ($P < .05$) (Table 3).

Earlier age at first sexual intercourse is strongly associated with a higher rate of having multiple recent partners for all never-married women except divorced/separated Whites. Among never-married White women, the percentage reporting multiple partners increases almost fivefold for those whose first intercourse was before age 15 (17.8%) compared with those whose first intercourse was after age 18 (3.8%). This association is also large among never-married Black women, substantially smaller among divorced/separated Black women, and nonexistent among divorced/separated White women.

Among never-married women, having two or more recent sex partners is reported most by those with no religious affiliation and least by those who attend religious services once a month or more; there is no such significant association among divorced/separated women. Among never-married Whites, those with no religious affiliation are more likely to have multiple partners than those with some affiliation (16.7% vs 7.4%; $P < .05$). Among never-married Blacks, lack of at least monthly attendance at religious services (compared with monthly attendance) is associated with having multiple recent partners (8.8% vs 4.3%; $P < .05$).

Among never-married White women, residence in the central city of a metropolitan area is associated with a significantly higher percentage reporting multiple recent sex partners (11.3%) than is suburban or nonmetropolitan residence (7.4%, $P < .05$). This is not true among Black women or divorced/separated women.

Multivariate Analysis

To control for the simultaneous effects of age, education, residence in a metropolitan area, age at first sexual intercourse, religious affiliation, and religiosity on the number of recent partners, we conducted multiple logistic regression analyses. Because of interactions among race, marital status, and the other variables, we conducted separate analyses for the four race–marital status groups.

Two key findings emerge from this analysis (Table 4). First, among sexually active women overall, early age at first sexual intercourse predicts a higher likelihood of having two or more sexual partners in the previous 3 months of sexual activity. After stratification by race and marital status, this finding remains significant for never-married women but does not hold for divorced/separated women. Second, religion is associated with having multiple recent sex partners both for women who have never married and for those who are divorced or separated. However, different measures of religion's effect are significant for Whites compared with Blacks: among Whites, religious affiliation independently predicts this behavior, while among Blacks regular attendance at religious services is predictive.

After controlling for the effects of other variables, the significant predictors

of having multiple recent sex partners among White women who have never married are early first sexual intercourse (younger than 18 years compared with 18 or older), central city residence, and having no religious affiliation. Among Black women who have never married, first sexual intercourse before 15 years of age and less than monthly attendance at religious services are predictive.

Independent predictors of having multiple recent partners among divorced/separated White women include any college education and having no religious affiliation. Among divorced/separated Black women, only less than monthly attendance at religious services predicts this behavior.

Discussion

We found that among sexually active women, less than 1 in 200 of those who are currently married and less than 1 in 10 of those who are currently unmarried report having multiple recent sexual partners. Marital status, socioeconomic status, central city residence, age at first sexual intercourse, religious affiliation, and religious attendance are associated with the expression of this sexual behavior. Furthermore, the effect of each of these factors is different among Black compared with White sexually active, unmarried women.

We studied four groups in detail in this analysis: never-married Whites, never-married Blacks, divorced/separated Whites, and divorced/separated Blacks. Race and marital status were singled out for stratification because these are generally accepted as markers of distinct patterns of sexual behavior[28] and because they provide discrete population subgroups for the targeting of STD interventions. Two variables stand out because their effects are strong and because their effects were found in multiple race–marital status groups: age at first sexual intercourse and the religious factors.

We found that earlier first intercourse predicts having multiple recent partners for never-married Whites and Blacks and for divorced/separated Blacks, even when the effects of other variables are controlled. Early first sexual intercourse has been associated with "risky" behaviors such as using drugs,[6,29] not using contraception at first intercourse,[30] having more sexual partners,[31,32] and having more frequent intercourse.[33,34] It may also be a marker for other sexual behaviors that place an individual at increased risk for STDs, such as lack of condom use, less discriminating sex partner recruitment, and having multiple sex partners in a short time period.[35] Finally, early age at first intercourse is directly linked to bacterial and viral STDs[1,2,36,37] and to cervical cancer and dysplasia.[38–41]

The association we have demonstrated between low religiosity and having multiple recent partners among unmarried Blacks, and between lack of religious af-

TABLE 4—Factors Associated with Having Two or More Recent Sexual Partners by Marital Status and Race: Results of Logistic Regression

	Odds Ratio	95% CI
Never-married Whites (n = 884)		
First sexual intercourse < 15 years of age (vs after 18 years)	6.6	2.4, 18.8
First sexual intercourse 15–17 years of age (vs after 18 years)	3.6	1.5, 8.8
Central city residence	2.3	1.3, 4.0
Lack of any religious affiliation	2.1	1.1, 4.3
Never-married Blacks (n = 1086)		
First sexual intercourse < 15 years of age (vs after 18 years)	4.4	2.0, 10.1
Less than monthly attendance at religious services	2.1	1.3, 3.4
Divorced/separated Whites (n = 499)		
Any college education	2.1	1.1, 4.0
Lack of any religious affiliation	3.4	1.3, 8.9
Divorced/separated Blacks (n = 441)		
Less than monthly attendance at religious services	2.0	1.0, 3.8

filiation and having multiple recent partners among unmarried Whites, suggests that the religious variables may be markers of women who are more apt to disregard behavioral norms with respect to sexual behavior. Having a religious affiliation and attending religious services frequently have been inversely associated with early first sexual intercourse,[29,42] number of partners in the preceding year (General Social Survey, 1988–1990, unpublished data), and coital frequency.[34] Some theorists view one's connection to religion as an indication of proneness to engage in socially acceptable behavior.[29,34] The relationship between such markers and risky behavior and their potential use in targeting interventions require further research.

In our data, some factors have particularly strong effects in some race–marital status groups, but not in others. For example, early first sexual intercourse and low religiosity, which predict having multiple recent partners among never-married women, are much weaker or unimportant as predictors among divorced/separated women. Educational level is positively associated with having multiple partners among divorced/separated White women, and negatively among never-married women. In addition, divorced/separated Black women are almost twice as likely to have multiple recent partners as are never-married Black women (11% vs 6%; $P < .05$). Thus, being formerly married (compared with never married) is associated with different predictors of having multiple recent partners, and also distinguishes some groups (e.g., Black women) at higher "risk" for having multiple partners.

Similarly, race is associated with different patterns of this behavior among unmarried, sexually active women. The data suggest different, though not necessarily riskier, practices among Black women compared with White women. The finding that having multiple recent sexual partners is most common among divorced/separated Black women (11.2%), least common among never-married Black women (6.2%), and intermediate among unmarried White women (9.0%) points to the oversimplification introduced by using race alone as a predictor of sexual behavior; stratification by marital status adds a new dimension to the discussion of such racial differences. An accurate appraisal of these differences is especially important for STD prevention activities because of the wide disparity in STD incidence between Blacks and Whites.

These self-reported data may contain bias. Intentional nonreporting, incomplete recall, and misunderstanding of the survey questions could lead to inaccuracies in self-reported number of sexual partners and result in underreporting of multiple partners. Thus, these findings probably represent minimum estimates of the number of recent sex partners. However, no representative database exists for comparison.

This analysis focuses on one high-risk behavior for STD acquisition (i.e., multiple current partners) and describes profiles of women who report this behavior and who should be targets for STD interventions. However, the contribution of behavioral factors to a woman's risk for STD acquisition must be seen in the context of the specific pathogen and the prevalence of that infection in her "partner pool." For most groups of women, in fact, STD rates do not parallel the prevalence of having multiple partners. Thus, although having two or more recent sex partners is clearly associated with STDs, factors such as condom use and the prevalence of disease in the partner pool also have important effects on STD acquisition.[43–45] Our data focus attention on the women who are at some elevated risk for STDs as a result of this specific behavior or other risky behaviors (e.g., indiscriminate partner recruitment)[12,20] for which having multiple recent partners may be a marker.

The charge of public health practitioners is to define high-risk behavior, describe high-risk populations, and design and implement appropriate interventions. This description of some characteristics of women who report having multiple recent partners allows practitioners and educators to promote safe sexual practices among certain target groups—such as younger women, unmarried women whose first sexual intercourse was before age 15, never-married White women who live in a city and/or have no religious affiliation, divorced/separated White women who are college educated, and unmarried Black women who did not finish high school. Early intervention focused on those most likely to exhibit such risky behavior can lead to a reduction in lifetime STD acquisition and transmission. Finally, clinical intervention (e.g., screening for asymptomatic STDs, high clinical index of suspicion for STDs) also can be appropriately targeted to reduce STD morbidity. □

Acknowledgments

The National Survey of Family Growth was supported by the National Center for Health Statistics, the Office of Population Affairs, and the National Institute for Child Health and Human Development, all of the US Department of Health and Human Services. These and other agencies also contributed to the design of the survey.

A portion of this research was presented at the annual meeting of the Society of Behavioral Medicine held in Washington, DC, March 1991.

We thank Willard Cates Jr, MD, MPH, Tom Peterman, MD, and William Darrow, PhD, for their critical reviews and insightful comments.

The Medical Origins of Homelessness

Marilyn A. Winkleby, PhD, Beverly Rockhill, MA, Darius Jatulis, MS, and Stephen P. Fortmann, MD

ABSTRACT

In 1989 through 1990, we conducted a cross-sectional survey of 1437 homeless adults in northern California (98% response rate). Prevalences of alcohol abuse, illegal drug use, and psychiatric hospitalization when adults first became homeless were 15% to 33% lower than prevalences following homelessness. The largest differences between the homeless and a comparison group of 3122 nonhomeless adults were for psychiatric hospitalization (odds ratios [ORs] of 4.6 for men and 5.9 for women) and alcohol abuse (ORs of 2.3 for men and 4.0 for women). However, when prehomeless prevalences of addictive and psychiatric disorders were compared with prevalences among the nonhomeless, absolute differences were no greater than 12%. (*Am J Public Health.* 1992;82:1395–1398)

Introduction

A consistent sociodemographic profile of homeless adults has emerged over the last decade indicating that the homeless are predominantly men in their 30s who have completed high school,[1,2] have few or no dependents,[3,4] and are long-term residents of the cities in which they reside.[1,2] Research on substance abuse[5–8] and psychiatric disorders[8–17] among the homeless is less consistent and remains the subject of considerable debate[8,18,19] because of two conceptual and analytic problems. First, with some exceptions,[15] addictive and psychiatric disorders that precede homelessness have not been distinguished from those that are a consequence of homelessness, thereby limiting the opportunity to explore causal hypotheses and to evaluate the accretion of disorders following homelessness. Second, many studies have not used comparative data on nonhomeless populations, thereby hindering the evaluation of the extent to which the homeless exhibit an excessive prevalence of medical disorders.

Methods

We conducted a cross-sectional survey of adults from the three National Guard armories in Santa Clara County, California, that provide approximately half of all shelter beds for adults in the county.[20,21] The largest armory (with a capacity of 300 persons) is located in downtown San Jose, the 13th largest city in the United States. The armories admit any adult without children, allow registration throughout the night, and impose no limits on the length of stay (the average stay per guest is 15 nights). Recruitment took place every night from November 26, 1989, through March 31, 1990. All persons were invited to participate on the first night they registered and were administered a 58-item questionnaire by nurses and health interviewers. To ensure that no one was interviewed twice, a master file was kept of names, ages, and interview status.

Demographic questions were adapted from the 1980 US census. Items on substance abuse were selected from the National Institute of Mental Health (NIMH) Diagnostic Interview Schedule (DIS), a structured questionnaire designed for lay interviewer administration.[22] The DIS questions examining excessive alcohol intake addressed both perceptual ("Did you ever think you were an excessive drinker?) and quantitative ("Did you ever consume

seven or more beers, drinks, or glasses of wine every day for two weeks or more?") aspects of drinking. The DIS question on drug use asked whether respondents had ever used illegal drugs (including opiates, cocaine, and marijuana) every day for 2 weeks or more. The psychiatric hospitalization question, selected from the NIMH Epidemiologic Catchment Area Study questionnaire,[23] asked whether respondents had ever been admitted overnight to a hospital or treatment program for family or personal problems, emotional problems, or problems with drugs or alcohol. These questions were adapted to distinguish whether addictive and psychiatric disorders preceded or followed the respondent's first episode of homelessness.

We compared our data with data for adults from three nonhomeless populations: (1) the Epidemiologic Catchment Area Study (the California DIS sample, n = 3122)[24]; (2) the 1980 California census, representing the general domiciled population[25]; and (3) a subset from the 1980 California census, representing a local impoverished domiciled population.[26] The last group is a census bureau statistical subarea and includes 64 430 adults from 23 low-income San Jose census tracts. Analyses comparing the homeless with the California DIS sample were stratified by sex and directly standardized for marital status because of large differences in prevalence by sex and disproportionate numbers of unmarried respondents among the homeless.[27]

To assess the reliability of respondents' answers, 35 individuals were randomly selected and reinterviewed at the conclusion of the study. All variables showed a high degree of agreement in the test/retest analysis; 100% for age first homeless and illegal drug use, 91% to 97% for adverse childhood events, and 86% to 89% for alcohol use and psychiatric hospitalization.

Results

Response Rate

Of the 1464 adults who registered at the armories, 1268 men and 169 women (n = 1437) completed the survey. The response rate was 98%, with no significant differences between respondents and nonrespondents by age, sex, or race ($P > .05$).

Homeless Characteristics

Most respondents first became homeless during young adulthood (47% before age 30, 78% before age 40). Forty-four percent had been homeless more than once, and 39% had spent more than 1 year without shelter (cumulative lifetime episodes). During the month before registering at the armories, 63% were literally homeless (i.e., their usual sleeping place was outside or in deserted buildings, in vehicles, or in shelters).

Sexually abused before age 18	6	33	9	...	...
Physically abused before age 18	13	28	14	...	...

[a]Includes those 25 years of age and older. When limited to those born in the United States, the percentages for the homeless population are 26% <high school, 41% high school, 25% some college, and 7% ≥4 years of college.

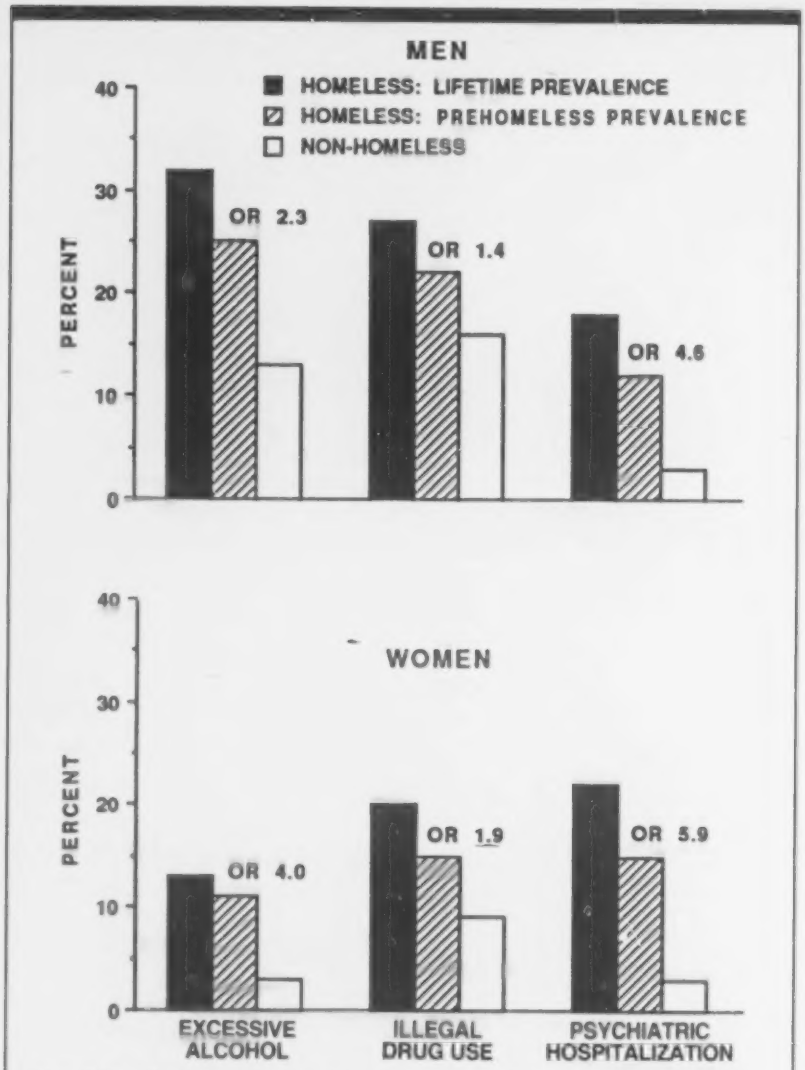
Sociodemographic Profile

Two thirds of the homeless were between the ages of 25 and 44 years (mean age = 36 years); virtually none were 65 or older (Table 1). Compared with the two nonhomeless census samples, African Americans were overrepresented and Asians were underrepresented among the homeless. The higher proportion of African Americans is consistent with their overrepresentation among the domiciled poor (e.g., 30% of African Americans live below the poverty level, compared with 9% of Caucasians),[25] and suggests that they may be more vulnerable to homelessness when affordable housing is scarce.[15] The small percentage of homeless Asians, however, is unexpected, given the recent influx of very poor Southeast Asian refugees to the area.

Sixty-eight percent of the homeless had completed at least high school and 30% had attended college. These levels of schooling increased when the analysis was restricted to respondents born in the United States (of whom 73% had completed high school and 32% had attended college). Compared with the nonhomeless impoverished sample, the homeless were less likely to have dropped out of high school; however, compared with Californians overall, the homeless had less education, especially at the college level.

Adverse Childhood Events

Ten percent of the men and 17% of the women had been removed from their parents and placed in foster care before the age of 18 (46% of these respondents were removed before age 10 and 54% at age 10 or older). Two general questions ("Were you ever physically abused before age 18?" and "Were you ever sexually



Note. Odds ratios (OR) compare prehomeless prevalences to nonhomeless prevalences.

FIGURE 1—Prevalences of excessive alcohol intake, illegal drug use, and psychiatric hospitalization among the homeless and the nonhomeless (California Diagnostic Interview Schedule sample).

abused before age 18?") indicated that 6% of the men and 33% of the women had been sexually abused and that 13% of the men and 28% of the women had been physically abused. Thirty-eight percent of those reporting physical abuse and 39% of those reporting sexual abuse had also been placed in foster care.

Adult Addictive and Psychiatric Disorders

Prevalences of excessive alcohol intake (determined on the basis of the quantitative alcohol question), illegal drug use, and psychiatric hospitalization before homelessness were 15% to 33% lower than lifetime prevalences (Figure 1). When comparing addictive and psychiatric disorders of the homeless before their initial loss of shelter (prehomeless prevalences) with those of the nonhomeless, the largest differences in prevalences were for alcohol intake (odds ratios [ORs] of 2.3 for men and 4.0 for women) and psychiatric hospitalization (ORs of 4.6 for men and 5.9 for women). ORs were 1.7 for both men and women when the perceptual alcohol question was used. Illegal drug use showed the smallest difference between the homeless before their initial loss of shelter and the nonhomeless (ORs = 1.4 for men and 1.9 for women). Despite the higher prevalences of addictive disorders and psychiatric hospitalization among the homeless than among the nonhomeless, absolute differences were no larger than 12 percentage points.

Forty-eight percent of the men and 63% of the women entered homelessness with no adult medical disorders (alcohol or drug abuse or psychiatric hospitalization); and 80% of the men and 59% of the women entered homelessness with no history of adverse childhood events (placement in foster care or sexual or physical abuse). To test which adverse childhood events and adult medical disorders were most strongly related to total time homeless, these factors were entered simultaneously into an ordinal logistic regression model[28] that adjusted for years of education. Excessive alcohol use as an adult and physical abuse during childhood were the factors most strongly related to length of time homeless (*P*s = .003 and .006, respectively).

Discussion

Although the prevalences of addictive and psychiatric disorders were higher among the homeless than among the nonhomeless, the differences may not be as great as previously reported. The prevalences of substance abuse and psychiatric hospitalization before homelessness (the prevalence rates most appropriate for studying causal hypotheses) were 15% to 33% lower than lifetime prevalences (the rates reported by most homeless studies). Furthermore, when the prehomeless prevalences were compared with prevalences among the nonhomeless, absolute differences were no greater than 12%.

Limitations

The following limitations should be considered. First, our findings are based on a cross-sectional study design rather than on a more definitive prospective design. Second, our assessments of substance abuse and psychiatric hospitalization are based on several standardized questions, possibly resulting in an underestimation of adult medical disorders in both the homeless and nonhomeless comparison groups. Investigators have, however, validated 3 of the 23 DIS questions on alcohol abuse against the Diagnostic and Statistical Manual of Mental Disorders, third edition (DSM-III), in a California homeless population[29] and found high sensitivity (94%), specificity (85%), and predictive value (91%). Third, although we used psychiatric hospitaliza-

tion as a measure of mental disorders because of its frequent use in past studies[2,30] and because it allowed for a valid comparison among the homeless and nonhomeless samples, we support the views of previous investigators who have emphasized the importance of structured clinical interviews to diagnose mental disorders,[10,18,22] and we recognize that psychiatric hospitalization does not serve as a direct marker for mental illness. In addition, the NIMH question on psychiatric hospitalization does not distinguish hospitalization for psychiatric problems from hospitalization for substance abuse problems. Finally, the generalizability of our results is unknown, because we sampled only shelter users. However, data we obtained from a telephone survey of homeless shelter and soup kitchen managers in the county (n = 15) and from a pretest survey of homeless men living in a riverbank encampment (n = 20) suggest that there are not important differences in prevalences of addictive and psychiatric disorders between shelter users and non–shelter users. Nevertheless, our sample, which included only adults without children, may be unrepresentative of homeless populations from other geographic areas, especially those from urban inner cities.

Consistency of Findings

Our sample appears quite similar to other homeless samples in regard to age (mean age of our respondents was 36 years, the same age as averaged over 23 studies)[2] and ethnic representation (49% of our respondents were minorities, compared with 44% of the homeless populations from the National Shelter Survey).[31] The lifetime prevalences of medical disorders we found are also in agreement with those found in past work, with approximately one in three persons reporting excessive alcohol intake and one in four to five reporting illegal drug use or psychiatric hospitalization.[2,30] In addition, the prevalences of medical disorders preceding homelessness found here mirror those reported by a previous study that sampled first-time shelter users and included a subsample of men interviewed on the first night they were homeless (n = 56).[15] In that study, the prevalence of psychotic disorders was lowest in the newly homeless and increased with length of time homeless.

Conclusions

Our results suggest that the homeless are less deviant in terms of social, addictive, and psychiatric pathology than has previously been proposed. Furthermore, our findings illustrate the need to examine disorders antecedent to the loss of shelter and to present comparative data on nonhomeless populations. □

Acknowledgments

This research was supported by grants from The Valley Foundation, the Community Foundation of Santa Clara County, the John Arrillaga Foundation, and the Komes Foundation.

This paper was presented at the 119th annual meeting of the American Public Health Association, Atlanta, Ga, November 10–14, 1991.

We are indebted to Barry Del Buono of the Emergency Housing Consortium and John Hall of the Health Care for the Homeless Project for access to the study population; to Byron Brown, Jr, for statistical consultation; and to Michael Fischetti, Andrew Zolopa, Erica Frank, and Sanford Dornbusch for their advice on the manuscript.

The Robert Wood Johnson Foundation's Call for Proposals on Health Care Financing

The Robert Wood Johnson Foundation is requesting proposals for research, demonstration, and evaluation projects that will produce information useful for policymakers regarding major changes in health care financing. This call for proposals is intended to stimulate projects that: (1) examine the effects of current mechaniams for, and proposed major changes in, the financing of health services on health care costs, access, and quality; and (2) develop and test new ways to finance care that have the potential to improve access to more affordable health services. Up to $12 million will be made available over 3 years for this initiative. Ultimately, the foundation hopes the results of these projects will be timely and useful for policymakers, public and private.

To be considered favorably, proposals must have the clear objective of examining major issues in health care financing and their effects on costs, access, or quality. Proposals will be assessed using the following criteria:

- the policy significance of the health care financing mechanism being evaluated or tested;
- the timeliness of the project for informing policy or practice;
- the quality and availability of data to be used, and the strength of the proposed methodology (depending on the focus of the project, primary data collection may be supported or the use of secondary data may be acceptable);
- the uniqueness of the project;
- the applicant's experience and qualifications for conducting the proposed project and the time commitment of key project staff who have the skills and experience to perform the various operations and analytic tasks required.

Preference will be given to applicants that are public agencies or are tax-exempt under Section 501(c)(3) of the Internal Revenue Code and are not private foundations as defined under Section 509(a).

Letters of intent will be accepted under this solicitation through May 1995 or until authorized funds are awarded, whichever comes earlier. For more information, contact Alpha Center, attn: HCFO, Suite 1100, 1350 Connecticut Ave NW, Washington, DC 20036; tel. (202) 296-1818; fax (202) 296-1825.
